"L'un des phénomènes les plus remarquables du système du monde est celui de tous les mouvements de rotation et de révolution des planètes et des satellites dans le sens de la rotation du soleil et à peu près dans le plan de son équateur. Un phénomène aussi remarquable n'est point l'effet du hazard, il indique une cause générale qui a déterminé tous ces mouvements \* \* \*

"Un autre phénomène également remarquable du système solaire est le peu d'excentricité des orbes des planètes et des satellites, tandis que ceux des comètes sont très allongés \* \* \*

"Quelle est cette cause primitive? J'exposerai sur cela, dans la note qui termine cet ouvrage (Système du Monde) une hypothèse, qui me paraît résulter avec une quande vraisemblance des phénomènes précédents, mais que je présente avec la défiance que doit inspirer tout ce qui n'est point un résultat de l'observation ou de calcul"

LAPLACE

### INTRODUCTION.

ONE hundred years ago LAPLACE published an outline of the nebular hypothesis, which has since been confirmed and developed by the labors of His physical explanation of the evolution of the planets and satellites, under the gradual operation of the laws of nature, was the logical outcome of his profound study of the mechanism of our system, and rested mainly on the common direction of motion and the small eccentricities and mutual inclinations of the orbits. From the concurrence of such remarkable phenomena in a great number of bodies the author of the Mécanique Céleste was led to conceive that at a remote epoch in the past, the matter now constituting the planets and satellites was expanded into a vast rotating fiery nebula, which slowly contracted with the radiation of its heat into surrounding space. Accordmg to the mechanical principle of the conservation of areas, the contraction accelerated the rotation and thereby increased the oblateness; when the centrifugal force at the equator became equal to the force of gravity the particles ceased to fall towards the centre, and the nebula shed successive rings or zones of vapor from its equatorial periphery The condensation of the several rings thus abandoned by the contracting mass eventually gave rise to the bodies of the planetary system.

LAPLACE observed that the comets, unlike the planets and satellites, have every degree of inclination and very high eccentricities, and hence he concluded that they were originally foreign to the solar system; accordingly, in the nebular hypothesis, the comets are regarded as small nebulae which have been drawn to the sun in its secular motion among the fixed stars.

The above hypothesis, based on sound dynamical principles and worked out in detail by the philosophic judgement and imaginative genius of Laplace, has merited and received the attention of subsequent natural philosophers. Owing to the brief duration of human history compared to the immense ages required for appreciable cosmogonic changes, probably the evolution of the heavenly bodies can never be observed, but must be inferred from a compara-

tive study of existing phenomena; and hence the sublime discovery of the essential process involved in the formation of the planetary system would necessarily mark an epoch in the history of science. The boldness and profound physical insight with which Laplace attacked this problem have justly ranked his effort among the greatest achievements of the human intellect. The germ of the general theory of evolution, which has so powerfully influenced the thought of the nineteenth century, may be traced to the recondite speculations of this great geometer.

The strikingly analogous cosmogonic views advanced by Kant in the Naturgeschichte und Theorie des Himmels preceded those of Laplace by fortyone years, and hence some priority is claimed for the great metaphysician of Konigsberg, but since the real vitality of the nebular hypothesis springs from Laplace, whose scientific eminence gave it authority commensurate with the development of Physical Astronomy in the eighteenth century, this great cosmogonic speculation is justly dated from the publication of the Système du Monde in 1796.

SIR WILLIAM HERSCHEL'S observations on the different types of stars and nebulae led him to consider them of different ages, and to compare the heavenly bodies in such various stages of development to the mixture of growth and decay presented by the trees of an aged forest. The combination of Herschel's studies on actual phenomena of the heavens with LAPLACE'S dynamical speculations relative to the solar system gave the nebular hypothesis both an observational and a theoretical basis, and hence it soon became an integral part of scientific Sir John Herschel's survey of the entire heavens supplied new philosophy. and important observations relative to the appearances of the stars and nebulae, and confirmed the general validity of the nebular hypothesis. When, however, Lord Rosse's great Reflector resolved certain clusters previously classed as nebulae, the question naturally arose whether with sufficient power all nebulae might not be resolved into discrete stars Fortunately, the invention of the Spectroscope about 1860, and Huggins's application of it to the heavenly bodies, showed that many of the nebulae are masses of glowing gas gradually condensing into stars, and, so far as possible, realized the postulates laid down by Laplace Joule's discovery of the mechanical equivalent of heat and Helmholtz's application of the resulting laws of thermodynamics to the heat of the sun, established the contraction of the solar nebula, while the subsequent researches of LANE, NEWCOMB, KELVIN and DARWIN have shown the theoretical possibility of most of the development outlined in the Système du Monde.

Notwithstanding the general confirmation of the essential parts of Laplace's speculation, some doubt still remains whether the planets and satellites separated as rings or as lumpy masses, and whether rings of anything like regularity could ever condense into single bodies. The most recent investigations of this question indicate that instead of separating as rings or zones which afterwards condensed, the planets and satellites, like the double stars, assumed originally the form of lumpy or globular masses

In the time of LAPLACE it was supposed that the figures of equilibrium of rotating masses of fluid, whose particles attract one another according to the Newtonian law, are of necessity surfaces of revolution about the axis of rotation, and therefore that a separation could take place only in the form of But the investigations of JACOBI showed that a homogeneous mass of fluid in the form of an ellipsoid of three unequal axes rotating about its shortest axis could be maintained in equilibrium by the pressure and attraction of its parts, the figure of such a mass is no longer one of revolution, although it is still symmetrical with respect to the axis of rotation. Poincaré's recent investigation of the stability of the equilibrium of the Jacobian ellipsoid showed that when the oblateness has become about two-fifths the equilibrium in this form becomes unstable, and another figure is developed; the body assumes the form of a pear or an hour-glass with two unequal bulbs, and finally breaks up into two comparable, though unequal, masses. from an entirely different point of view, DARWIN made an independent and almost simultaneous investigation of the form assumed by the mass after the Jacobian ellipsoid becomes unstable. Taking two separate masses of fluid revolving as a rigid system in such close proximity that the tidal distortions of figure cause them to coalesce, he determined the resulting figure of equilibrium, and found a dumb-bell form corresponding very closely to the  $\Lambda$ pioid discovered Though both of these investigations relate to homogeneous by Poincaré. masses, and therefore are not strictly applicable to the cases which arise in nature, yet they agree entirely in proving the existence of unsymmetrical forms of equilibrium; and a comparison of these figures with the drawings of double nebulae made by Sir John Herschel leaves no doubt that the process of separation into unequal but comparable masses indicated by these recondite mathematical researches is abundantly illustrated in the evolution of double stars from double nebulae. If this process has played such a prominent part in the genesis of the stellar systems, it is highly probable that the planets and satellites originated in a similar manner, notwithstanding the abnormally rapid increase in density towards the centres of the solar nebula implied by the separation of such inconsiderable masses.

When NEWTON established the law of universal gravitation he also discovered the true cause of the tides of the sea, and outlined some of the principal phenomena which follow from the perturbing action of the sun and moon upon the waters which cover the terrestrial spheroid After the lapse of more than a century LAPLACE attacked this problem from the dynamical point of view, and developed his celebrated analytical theory of oceanic tides, which has been generally adopted in the subsequent researches of astronomers. About two centuries after Newton established the cause of the tides, Darwin was led to consider not only the tides in the mass of fluid spread over the earth's surface, but also those which arise in the body of the globe, owing to its imperfect rigidity He inquired whether the earth's mass might not be a fluid of great viscosity, and proceeded to develop the theory of bodily tides, and to discuss the bearing of these researches on the cosmogonic history of the earth and moon When the investigation was subsequently extended to other parts of our system, it was found that while Laplace's hypothesis as a whole remained unshaken, some appreciable modifications were rendered necessary, especially in the case of the earth and moon, where the relatively large mass-ratio of the component bodies sensibly increased the efficiency of tidal friction. It seemed clear that in the development of the lunar-terrestrial system, the action of tidal friction had been of paramount importance, but that elsewhere the effects had been much less considerable, owing chiefly to the small masses of the attendant bodies

When we reflect that the planetary system is made up of a great number of very small bodies revolving in almost circular orbits about large central masses, and is therefore different from all other known systems in the heavens, although other systems like it may exist unobserved, it is remarkable that previous investigators have almost invariably approached the problems of Cosmogony from the point of view of the planets and satellites, and that no considerable attempt has been made to inquire into the development of the great number of systems observed among the fixed stars The short period of time which has elapsed since the explorations of the Telescope have inade known the general state of the heavens, with the impossibility of observing any considerable changes, except in the case of double stars, may perhaps account for the natural tendency to focus all effort upon the development of the planets and satellites But the peculiar character of our system, compared to other known systems in space, ienders this procedure incapable of giving us any general law of nature It is only from a study of the systems of the universe at large that we may hope to throw light upon the general problems of Cosmogony, among these systems the binary stars are eminently suited for such an investigation

In the present work we propose to investigate the evolution of the stellar systems. The problem is difficult and the observations are incomplete, and hence in this arduous undertaking we may beg the indulgence of astronomers for such imperfections as the discussion of the subject will necessarily exhibit. The present volume is devoted mainly to the facts as made known by the labors of double-star observers since the time of Sir William Herschel, the more theoretical inquiry into the Secular Effects of Tidal Friction and the Processes of Cosmogony is reserved for subsequent treatment

It would seem that the micrometrical measures discussed in this work establish for the first time, on a secure observational basis, the general shape of the real orbits of double stars. It follows from the results here brought to light that the most probable eccentricity among double stars is over 0.45, and since this mean value is deduced from the consideration of forty orbits, which future observations will not alter materially, we see that such high eccentricities are characteristic of the stellar systems. In the solar system the mean eccentricity for the great planets and their satellites does not surpass 0.0389, and hence we see that the average eccentricity among double stars is about twelve times that found in our own system. The great number of binary stars and the practical certainty that the properties deduced from forty of the best orbits now available will be confirmed by the stellar systems in general, justifies us in raising this remarkable induction, relative to the eccentricities, to the dignity of a fundamental law of nature. The binary stars are therefore distinguished from the planets and satellites by two striking characteristics.

- I The orbits are highly eccentric
- 2. The stars of a system are comparable, and frequently almost equal, in mass

The first of these remarkable properties is traced mainly to the condition stated in the second, high eccentricities probably did not belong to these systems originally, but have been *developed* by the secular action of tidal friction, which is a physical cause affecting all cosmical systems.

In developing the theory of gravitation mathematicians have very generally assumed that the attracting masses are rigid solids, and hence it has been easy to overlook the fact that nearly all the bodies of the visible universe are really fluid. The stars and nebulae are self-luminous masses of a gaseous, liquid or

semi-solid nature, and hence it is apparent that in such systems enormous bodily tides will necessarily arise from the mutual gravitation of the particles are cosmic phenomena as universal as gravitation itself; and since tidal friction will operate in every system of fluid bodies which is endowed with a relative motion of its parts, we see that the general agency of bodily tides gives rise to most important secular changes in the figures and motions of the heavenly The tidal alterations of figure, which modify the attraction on neighboring bodies bodies, will become especially marked in the case of double stars and double nebulae, where two large fluid masses in comparative proximity are subjected to then mutual gravitation, and hence if the bodies of such a system be rotating as well as revolving the secular working of tidal friction becomes an agency of great and indeed of paramount importance. The general theory of all the secular changes which follow from the double tidal action arising in a binary system remains to be developed, but meanwhile the work of DARWIN in connection with the extension which I have given his researches, makes known some of the more important effects

From our previous investigations it seems exceedingly probable that the great eccentricities now observed among double stars have arisen from the action of tidal friction during immense ages, that the elongation of the real orbits, so unmistakably indicated by the apparent ellipses described by the stars, is the visible trace of a physical cause which has been working for millions of years. It appears that the orbits were originally nearly circular, and that under the working of the tides in the bodies of the stars they have been gradually expanded and rendered more and more eccentric.

Some simple considerations will enable us to see how these general results arise from the secular action of tidal friction. Suppose the two stars of a system to be spheroidal fluid masses of small viscosity, and let us assume, conformably to the motions observed in the solar system and to those which would result from the division of a double nebula, that the two bodies are rotating about axes nearly perpendicular to the plane of orbital motion, and in the same direction as the revolution about the common centre of gravity, also let the angular velocity of rotation considerably surpass that of orbital revolution. Then, as the fluid is viscous, the tides raised in either mass by the attraction of the other will lag, and hence the major axes of the tidal ellipsoids will point in advance of the tide-raising bodies, and the tidal elevations will exercise on them tangential disturbing forces which tend to accelerate the instantaneous velocities and thereby increase the mean distance. The reaction of the revolving bodies upon the tidal protuberances will retail the axial rotations; for the

moment of momentum of the whole system is constant, and the moment of momentum of axial rotation lost by the stars must be just equal to the gain in moment of momentum of orbital motion. Thus the rotations of the stars are diminished, while the mean distance is correspondingly increased.

But the tangential disturbing force is found to vary inversely as the seventh power of the distance, and hence when the orbit is eccentric the accelerating force at penastron is very much greater than at apastron. The result is that at penastron the disturbing force increases the apastron distance by an abnormally large amount, while at apastron it increases the penastron distance by a very small amount. Thus while the ellipse is being gradually expanded, the apastron is driven away so rapidly compared to the slight recession of the penastron that the orbit grows more and more eccentric. When the axial rotations are sufficiently reduced by the transfer of axial to orbital moment of momentum this change of the system will finally cease, under conditions different from those mentioned above the eccentricity and major axis may decrease, and various other changes take place

The causes here briefly sketched appear to be sufficient to account for the development of double stars, and the tidal theory might therefore be regarded as satisfactory, yet if the explanation be deemed incomplete it is easy to adduce considerations which exclude other conceivable hypotheses. Let us imagine the x-axis to represent the region of eccentricity, and divide this line into convenient parts, making the intervals, say, 01, then we may erect ordinates denoting the number of orbits falling in a given region, and thus illustrate the distribution of orbits as regards the eccentricity. The irregular line which results from connecting the points determined by a finite number of orbits would become a smooth curve if the number were indefinitely increased. In case of the double stars we obtain what is essentially a probability curve with the maximum near 0.45; the slope on either side appears to be somewhat gradual, but the curve vanishes at zero and unity

If we make a similar representation for the orbits of comets, we shall find a very high maximum at the eccentricity unity; in this case both slopes are extraordinarily steep, though perhaps the curve descends with less rapidity on the side towards the origin, on account of the considerable number of periodic comets which have been gradually accumulated by the perturbing action of the planets. The corresponding curve for the planets and satellites has a high maximum near 0 0389, and while both slopes are steep, that on the side from the origin is the more gradual by virtue of the somewhat unusual eccentricities of Hyperion, the Moon and Mercury

If we inquire into the physical meaning of these illustrations, it is easy to see that the distribution of the cometary orbits about the parabolic eccentricity indicates, as LAPLACE first pointed out, that the comets have been drawn to our system from the regions of the fixed stars. The curve for the planets and satellites proves merely that the eccentricities were originally small, and that, under the minimized effects of tidal friction resulting from such inconsiderable masses, they have never been much increased The curve for the orbits of double stars is of such a nature that we cannot, as in the case of comets, assign to these systems a fortuitous origin, for in this event the eccentricities would surpass, equal or approximate unity, and the periods of revolution, if finite, would be of immense duration, nor could any cause be assigned for the reduction of the eccentricity and period if it be admitted that anything which might properly be called a system could arise from the approach of separate stars other hand the stellar orbits have no close analogy with those of the planets and satellites, for they are densest in the region of mean elliptic eccentricity, and thus almost equally removed from the two extremes presented in the solar They were therefore of this mean form originally, or have been made so by a cause which has left a distinct impress upon the nature of the systems The secular alteration in the figure of equilibrium of a greatly expanded mass like a double nebula would of necessity be very gradual, and hence it follows that the mass cut off under the increased centufugal force incident to slowly accelerated rotation would begin to revolve in an orbit of comparatively small Indeed, were the initial eccentricity considerable the two nebulae would come into grazing collision at periastron, and in consequence of the resistance encountered the system would rapidly degenerate into a single mass When at length the bodies are separated, each mass will contract and gain correspondingly in velocity of axial rotation, and tidal friction will begin expandmg and elongating the orbit, nothing but this secular process would be adequate to develop the mean eccentricities observed in the immensity of space tidal friction be sufficient to account for the elongation of the real orbits of double stars, we shall be justified in concluding that it is the true cause of the phenomenon Accordingly, it does not seem probable that the conclusions reached in the Inaugural Dissertation which I presented to the Faculty of the University of Berlin will be materially altered, but some of the many problems connected with the general theory of tides still need additional elucidation If we shall be able to explain the origin and development of double stars, the abundance of such systems will raise a presumption that the agencies and processes involved are more or less general throughout the universe, and no inconsiderable light

will be thrown upon the laws of Cosmogony. By extending our researches to the various classes of nebulae and clusters, additional knowledge will be gained, and in the course of time it will be possible to approach the general problem of cosmical evolution.

For more than two centures Celestial Mechanics has been occupied with the confirmation of the Newtonian law, and with the development of theories for the precise determination of the figures and motions of the heavenly bodies. In the writings of Newton and Laplace the attracting masses are essentially solid spheroids covered by a fluid in equilibrium. The theories of the orbital motions and perturbations of the planets, and of the figures and rotations of these bodies about their centres of gravity, are treated mainly from the point of view of rigid dynamics, and little account is taken of the fact that so far as known the heavenly bodies are masses of viscous fluid. The work of Darwin on the precession of a viscous spheroid and on the secular effects of bodily tidal friction marks an epoch in the history of Celestial Mechanics, which will eventually become a science of the equilibrium and motion of fluids, and must take account of not only the attractions due to undisturbed figures, but also the forces arising from tidal deformation, with the resulting secular changes in the motions of the heavenly bodies.

Physical Astronomy has been devoted heretofore to first approximations under the law of universal gravitation, in particular, to the development of methods for tracing the exact paths of the heavenly bodies through past and future centuries; the theories thus developed are applicable to all periods of recorded history and are justly considered the most imposing monuments yet reared by the human intellect. But the ultimate aim of Astronomy is not only to explain and to predict phenomena which the course of time will make known to observers, but also to determine the secular effects of cumulative causes, and, by approaching the primitive condition of the universe, to discover the origin and to trace the evolutionary history of the stars. As the slow processes of cosmical development are forever withheld from the direct vision of the astronomer, and can be discovered only by the investigation of the continued effects of laws and causes now at work in the heavens, the solution of this sublime problem will be an achievement not unworthy of the human mind

Hawley House, 5326 Washington Ave, Chicago, May 6, 1896

### CHAPTER I.

On the Development of Double-Star Astronomy, and on the Mathematical Theories of the Motions of Binary Stars.

#### § 1 Historical Sketch of Double-Star Astronomy from Herschel to Burnham.

The suggestive relation of certain prominent stars, in contrast with the irregular manner in which the multitude are strewn over the surface of the celestral sphere, presented to the minds of the ancients the appearance of arrangement or classification, the more or less obvious constellations thus invented for bright and widely-separated objects were of various sizes, and frequently of an arbitrary character The condensation of the stars into natural groups, such as the Pleiades, Coma Berenices, and the clouds in the Milky Way, must have attracted early attention, but no one attempted a philosophical inquiry into the cause of such arrangement until Mitchell took up the question in 1767, and showed from the theory of probability that a real physical connection was strongly indicated Further considerations of a similar character led him to predict in advance of observation that compound stars would be found nevolving about their common centres of gravity LAMBERT had surmised the existence of possible stellar systems in 1761, and Giordano Bruno, Cassini, and Maupertuis had advanced even earlier conjectures of the same The argument for physical connection of closely associated stars, based on the theory of probability, has since been greatly extended by WILLIAM STRUVE, and a practical verification of theory is furnished by the evidence of orbital motion in about 500 out of the 5000 interesting double stars catalogued by modern observers

The designation double-star ( $\delta\iota\pi\lambda\circ\hat{\nu}s$ ) was first employed by Ptolemy in describing the appearance of  $\nu$  Sagittarii. The first object of the kind ever discovered with the Telescope was probably  $\zeta$  Ursae Majoris, which appeared double to Riccioli about the middle of the seventeenth century. The quadruple system  $\theta$  Orionis was detected by Huyghens in 1656, and the wide pair  $\gamma$  Arietis by Hooke some eight years later. While observing a comet at Pondicherry, India, in December, 1689, Father Richaud separated the com-

ponents of a Centauri, and thus seemed the first record of a star, which has proved to be binary. The duplicity of  $\gamma$  Virginis was accidentally discovered by Bradley and Pound in 1718, and subsequently re-discovered by Cassini and Messier, while observing occultations, with a view of finding evidence of an atmosphere surrounding the moon

a Geminorum was resolved in 1719, 61 Cygni in 1753, and  $\beta$  Cygni in 1755, but although these spotadic discoveries had been made, no systematic search for double stars was attempted until 1777, when Christian Mayer, of Mannheim, began to collect a list of these remarkable objects. Having reached the conclusion that faint stars near larger ones are essentially revolving planets, he searched the heavens attentively with an eight-feet mural circle, by Bird, and discovered in all some seventy-two pairs, including  $\gamma$  Andromedue,  $\zeta$  Cancre, a Herculis,  $\epsilon$  Lyrae and  $\beta$  Cygni. Unfortunately, the wide objects within the reach of such a telescope seldom have any appreciable relative motion, and hence the stars discovered by Mayer give very little evidence of the physical connection which he expected

The real history of double-star discovery and measurement, dates from the explorations begun by Sir William Herschel in 1779 This indefatigable observer sought to grapple with the unsolved problem of stellar parallax, which had engaged the attention of astronomers since the time of Copernicus Rejecting the methods recommended by GALILEO, FLAMSTEED and BRADLEY, he proposed one of his own, depending on the measurement of position-angles of two stars of unequal magnitudes from opposite sides of the earth's orbit HERSCHEL supposed the double stars to be mere groups of perspective, and hence he hoped to detect the relative parallax due to the orbital motion of the He resolved to examine every star in the heavens with the utmost attention under a very high power, the superiority of his telescope gave him an advantage over previous observers, and moreover, his improved optical appliances were supplemented by great energy and boundless enthusiasm During the interval from 1779 to 1784 he made an extensive catalogue of double stars, some of which he hoped would ultimately prove to be suitable for measurement of parallax In 1782 he communicated to the Royal Society a catalogue of 269 double stars, 227 of which were new, and followed it three years later by a second catalogue containing 434 such objects. For the next fifteen years the attention of the great observer was devoted to, among other things, the measurement of these pairs, with a view of finding those best adapted to parallax determination Slight changes were observed from the first, but in most cases the shifting of the relative positions of the objects was attributed

either to the proper motions of the stars, or to the secular motion of the sun The motions were so slow that it took the observations of many years to prove conclusively that certain double stars are moving in regular This unexpected and astonishing result was finally announced by Herschel in 1802, and demonstrated during the following year by his elaborate memoirs on binary stars These investigations supplied the first satisfactory evidence that some of the double stars constitute genuine stellar systems Herschel's celebrated papers maintained by the action of universal gravitation dealt with the motions of such objects as \( \xi Ursae Majoris, 70 Ophiuchi, \( \gamma Virginis, \) a Geminorum, η Coronae Borealis, ξ Bootis, η Cassiopeae, ζ Herculis, μ<sup>2</sup> Bootis; and in some cases assigned rough estimates of the periods of revolution. The interest in an announcement which opened up fields of inquiry of the widest scope, was fully commensurate with the inherent importance of the discovery, and yet, notwithstanding the splendor of the achievement, double stars were little observed during the first twenty years of this century

SIR JOHN HERSCHEL began some preliminary work on double stars in 1816, and was soon joined by SIR JAMES SOUTH. During the next ten years these two observers published several series of observations made either conjointly or separately, and when SIR JOHN HERSCHEL made his survey of the Southern Hemisphere, over 2000 pairs were discovered and roughly measured. The conscientious records which he has left us in the *Results* of his observations at the Cape of Good Hope, as well as the catalogues since published, and his elegant researches on the orbits of double stars, ensure to him a distinguished place among those astronomers who have labored to advance our knowledge of binary systems

The systematic survey of the part of the heavens between the north pole and fifteen degrees south declination, executed by William Struve between the years 1824 and 1836, will long remain the most important contribution to double-star Astronomy ever made by one man. The instrument used was the Dorpat 99-inch refractor by Fraunhoffer, the results furnished the material of the Mensurae Micrometricae which includes careful observations of 3112 double and multiple stars, besides records of his previous work with smaller instruments. The labors of William Struve abolished Herschel's cumbersome method of referring position-angles to the quadrants, and reduced double-star Astronomy to a scientific basis by reckning the angle continuously from 0° to 360°. Out of this extensive work grew other reforms, such as the superior classification and arrangement of the results, and in this way Struve laid the foundations of the subsequent development of the science.

Among the other observers who contributed to this branch of Astronomy prior to 1850, we may mention especially Madler, Bessel, and Dawes. The measures of Dawes take high rank for quality and serve as an example of what may be done by private observers with limited appliances. Other deceased observers especially deserving of mention for important contributions to the records of double-star Astronomy are Seccili, Kaiser, Knott, Englemann, Jedrzejewicz, and, above all, Baron Dembowski

Though the last-mentioned observer worked privately and with a small instrument, his measures are more extensive and perhaps more accurate than those of any other observer either living or dead. Covering the period from 1854 to 1878, the work included measures of all the pairs in the Mensurae Micrometricae accessible to his 7-inch glass, besides numerous observations of pairs more recently discovered by himself, Otto Struve, Burnham and Alvan Clark. The twenty thousand precise measures executed by this great astronomer were collected after his death, edited by Otto Struve and Schiaparelli, and published in two large quarto volumes by the Academia der Lyncer of Rome

Beginning prior to 1840 and extending over the next fifty years, the double-star work of the illustrious Otto Struve furnishes by far the longest and most homogeneous set of observations yet made by any astronomer. Besides records of the numerous stars discovered by himself and by his father, Otto Struve's work includes reliable data for the most important stars discovered by other previous and contemporary observers. Many of his own stars are close and have proved to be comparatively rapid, and hence will soon yield satisfactory orbits.

Among living observers the names of Otto Struve, Hall, Dunér, Schiaparelli, Tarrant, Bigourdan, Maw, Glasenapp, Tebbutt, Stone, Comstock, Knorre, Seabroke, Doberck, Perrotin, Hough, and Burnham will be familial to the leader. Each has contributed important material for the study of the stellar systems, but the work of Struve, Hall, Schiaparelli, and Burnham is especially important to the computer, as covering a long series of years and thus supplying homogeneous material for the determination of the orbits of revolving binaries.

Prior to 1870 it had been generally held by such authorities as Dawes that the subject of double stars was practically exhausted by the discoveries of the Herschiels and the systematic surveys of the Struves. As the latter had swept over all the brighter stars in the northern heavens, including about 140,000 objects, we may refer with a certain pleasure to the epoch-making discoveries since made by Burnham, who has detected nearly 1300 important pairs which had escaped all previous observers. Burnham's stars are either very close or

the companion is very faint, and their high importance lies in their rapid orbital motion. This characteristic of Burnham's stars has already enabled us to deduce a number of most interesting orbits. It is probable that during the next half century his stars will yield more good orbits than all the other stars previously discovered put together. When we remember that the aim of the observer is to determine the paths of the stars with a view of throwing light upon the character of the stellar systems, it is clear that the measurement of these close objects, which will yield a large number of orbits within a reasonable time, is the most pressing duty of the observer of the future. Many distinguished observers have devoted their attention to the sidereal studies begun by the Herschels and developed by the Struves, but none have labored more devotedly or achieved more splendid discoveries than the illustrious Burnham.

# §2 Laplace's Demonstration of the Law of Gravitation in the Planetary System

Suppose we denote by X and Y the forces which act on a planet, resolved along the coordinate axes, and directed towards the origin at the centre of the sun; let the plane of the orbit be taken as the plane of xy. Then we have, as the equations of motion,

$$\frac{d^2x}{dt^2} + X = 0 , \frac{d^2y}{dt^2} + Y = 0 (1)$$

If we multiply the first equation by -y, and the second by x, and add the results, we find

$$\frac{d(xdy - ydx)}{dt^2} + xY - yX = 0 (2)$$

But  $\frac{dy-ydx}{dt}$  is the double areal velocity, and by Kepler's law the areas described by the radius-vector of the planet are proportional to the time. Therefore we have

$$xY - yX = 0, (3)$$

or the forces X and Y are related as the coordinates x and y; which indicates that the attractive force is directed to the origin of coordinates. Therefore we conclude that the force which retains the planets in their orbits is directed to the centre of the sun

We may now investigate the law of this force at different distances. On multiplying the first of (1) by dx, and the second by dy, adding and integrating, we have

$$\frac{dx^2 + dy^2}{dt^2} + 2\int (Xdx + Ydy) = 0$$
 (4)

If we denote the double areal velocity by c, we shall have

$$dt = \frac{i \, dy - y \, dx}{t},$$

and hence the last equation gives

$$\frac{e^2(dx'+dy^2)}{(xdy-ydx)^2} + 2/(Xdx+Ydy) = 0$$
(5)

In polar coordinates,

$$t = t \cos r$$
,  $y = t \sin r$ ,  $t = \sqrt{t^2 + y}$ ,

and we find

$$dx^2 + dy^2 = r^2 dx^2 + dx^2$$
,  $x dy - y dx = r^2 dx$ 

If we now denote by F the central force which acts on the planet, we shall have

$$X - F \cos v$$
,  $Y = F \sin v$ ,  $F = \sqrt{X^2 + Y^2}$ 

Hence we get

$$Xdx + Ydy = F\cos v \left(\cos v dx + i\sin v dx\right) + F\sin v \left(\sin v dx + i\cos v dx\right) - Fdv$$

Therefore

$$\frac{\epsilon' \left( r' dv^2 + \epsilon h r' \right)}{r' dv^2} + 2 \int F dr = 0, \tag{6}$$

and we find

$$dv = \frac{cdr}{(\sqrt{-c'-2r^2/Fdr})} \tag{7}$$

If the force F were a known function of r, we might find v by the process of quadrature. But since the force is unknown, although the species of curve it causes the planets to describe is known, we may differentiate equation (6), and obtain

$$F = \frac{\epsilon'}{\epsilon^3} - \frac{\epsilon^2}{2} \frac{d \left\{ \frac{dr^2}{\tilde{r}^4 d\tilde{v}^2} \right\}}{dr}$$
(8)

KEPLER found from observation that the planets and comets respectively move in ellipses and parabolas, which are conic sections. The polar equation of a conic may be written

$$\frac{1}{r} = \frac{1 + e \cos(v - \omega)}{u(1 - e^2)},$$
 (9)

whence we find

$$\frac{dr}{r^2dr} = \frac{e \sin(v-\omega)}{a(1-r^2)},$$

or 
$$\frac{dr^2}{r^4 dv^2} = \frac{e^2 - e^2 \cos^2(r - \omega)}{\omega^2 (1 - e^2)^2}$$
 (10)

If we reduce the second member by (9),

$$e \cos(v-\omega) = -1 + \frac{\alpha(1-e^2)}{r}$$

we shall easily find

$$\frac{dr^2}{r^4 dv^2} = \frac{2}{\alpha r (1 - e^2)} - \frac{1}{r^2} - \frac{1}{\alpha^2 (1 - e^2)},$$

and hence we get

$$\frac{d\left\{\frac{dr^{2}}{r^{4}dv^{2}}\right\}}{dr} = -\frac{2}{ar^{2}(1-e^{2})} + \frac{2}{r^{3}}$$
(11)

Thus equation (8) becomes

$$F = \frac{c^2}{a(1-e^2)} \frac{1}{r^2} \tag{12}$$

Therefore we conclude that the force which causes the planets and comets to move in conic sections about the sun varies inversely as the square of the distance from the sun's centre. Such is the demonstration by which Laplace was led to the law of universal gravitation; it rests solely on phenomena, and is independent of any hypothesis. The original demonstration by Newton was based on geometrical methods, and is given in the *Principla*, Lib. I, Sec. III, Prop XI.

The laws of Kepler made use of in these demonstrations are taken as fundamental facts discovered from observation, but planetary observations in the time of Kepler were not sufficiently exact to ensure entire rigor in these laws, and besides no account was taken of the mutual gravitation of the planets. Hence it will be seen that the accuracy of the laws of Kepler, even in the time of Newton, could be maintained only within given limits

It is never possible to realize the conditions of undisturbed motion assumed by Kepler, and hence the problem presented to astronomers can be solved only by successive approximations. Assuming that the facts embodied in Kepler's laws are strictly true, Newton's reasoning shows that the law of gravitation is mathematically exact; if on the other hand we assume the accuracy of the law of Newton, we are led directly to the laws of Kepler as phenomena which would arise under the operation of gravitation. The laws of Kepler are sensibly correct, and on the admissible supposition that they are entirely rigorous,\* astronomers have applied the law of gravitation to the disturbed motions of the planets, with a view of explaining observed inequalities, and of discovering from theory other perturbations which have been subse-

<sup>\*</sup>The third law is here supposed to be corrected for the planetary masses neglected by Kepler

quently verified by observation. This development of the planetary theories has occupied the attention of astronomers for over two centuries, and in every case where doubt has arisen the accuracy of the Newtonian law has been verified.

The large of possible maccuracy has been gradually narrowed, until at present the data of Astronomy show that if the law of nature departs at all from that given by Newton, the deviation must be extremely slight. Indeed, the law of gravitation, taken in connection with its simplicity, is so thoroughly established as to authorize the belief that it is rigorously the law of nature. Its brilliant confirmation and extension since the time of Newton, especially by Laplace, leaves but few, and generally insignificant, motions yet unexplained, and since we know that the slightest deviation from the law of inverse squares would become very perceptible in the motions of the perihelia of the orbits of the planets and the periplaneta of the orbits of the satellites, and no such outstanding phenomena have been disclosed by observation, except in the case of the perihelion of the orbit of Mercury, which may be explained in a different manner, it is hardly possible to doubt that the few anomalous phenomena yet remaining will finally be explained in perfect accord with the law of Newton

The strongest proof of the rigor of this law is to be found in the fact that it accounts for both the regular and the inegular motions of the heavenly bodies, and in the hands of LAPLACE and his successors has become a means of discovery as real as observation itself

A law which explains satisfactorily the figures, the secular variations, and the delicate long-period inequalities of the planets, and above all the numerous perturbations to which the moon is subjected, certainly has a strong claim to be regarded as a fundamental law of nature, and is incontestibly the sublimest discovery yet achieved in any science

#### § 3 Investigation of the Law of Attraction in the Stellar Systems

The labors of Newton and Laplace on the mechanism of the solar system established the law of gravitation with all the rigor which modern observations could demand, but neither of these two great geometers attempted to apply this law to other systems existing in space. The close of the career of Laplace, just a century after that of Newton, marks an epoch in the verification of the Newtonian law, since in this year Savary devised the first method for determining the orbits of double stars, he justly based his theory on the principle

of gravitation which the author of the Mécanique Céleste had recently tested with such thoroughness for the regions about the sun traversed by the planets and comets The method developed by Savary has been improved and rendered more practical by the labors of subsequent geometers, and consequently at the present time there is no considerable body of phenomena which appear to be irreconcilable with the law of Newton Indeed, when proper allowance is made for the large but inevitable errors of our micrometrical measures, all modern observations of binary stars may be explained either by the theory of two bodies revolving under the law of gravitation, or by the action of unseen bodies perturbing the regular elliptical motion. This accordance of observation with theory, while it increases enormously the probability of the Newtonian law, does not furnish an independent criterion, and therefore it is desirable to ascertam the most general form of the expressions which will cause a particle to describe a come, so that we may determine whether any other law can explain the phenomena In the case of double stars, micrometrical measures enable us to study only the apparent orbits, which are projections of the real orbits upon the plane tangent to the celestral sphere The apparent orbits are ellipses, and therefore we may conclude that the real orbits are also comes of the same species. When the orbit is projected the centre of the real ellipse will fall upon the centre of the apparent ellipse, but the positions of the projected foci are not determinate unless the position of the real ellipse is known Astronomers are accustomed to assume that Newtoman gravitation is the attractive force, and as this requires that the principal star shall be in the focus of the real ellipse, it then becomes easy to deduce the corresponding node, inclination and other elements. It is observed that the principal star is not in the centre of the ellipse, and therefore we infer that the force does not vary directly as the distance But since the areas swept over by the radius vector are proportional to the times, we may conclude that the force is central, and since the appaient motion of 42 Comæ Beremees is rectilinear, it is clear that the orbit is a plane curve, or conic section. As other forces besides gravitation could cause a particle to describe a come, Bertrand proposed the following problem to the Paris Academy of Sciences "Knowing that a material particle under the action of a central force always describes a conic, it is required to find the expression of this force."\*

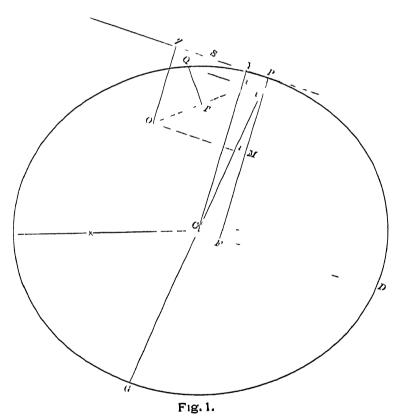

Before presenting the solutions developed by Darboux and Halphen, we shall give an exposition of the geometrical method by which Newton treated the same problem

In the Scholium to Proposition XVII, Liber I, of the Principia, Newton

<sup>\*</sup> Comptes Rendus, April 9, 1887

derived the general expression for the force which will cause a particle to describe a come section, the centre of force occupying any internal point. The demonstration given by Newton depends upon several preceding propositions, a more direct but similar solution of the same problem has been published by Professor Glassier in the *Monthly Notices*, Vol. XXXIX

This investigation is as follows. Let C be the centre of the ellipse, P any point occupied by the particle, Q the point occupied by the particle at the next instant, PZ the tangent at P, PG the diameter through P, CD the semi-conjugate diameter to PG, O the centre of attraction, QS a right line parallel

to OP, OZ and CY perpendiculars on the tangent from O and C, PF the perpendicular on CD from P, QT the perpendicular from Q on OP, Qr and OM perpendiculars on PF from Q and O, r the intersection of Qr with OP, r the intersection of OM with OP, and R the required force tending to O.

Then we shall have

$$R = \frac{2h^2}{OP^2} \frac{QS}{Q\bar{F}^2},\tag{1}$$

where h denotes the areal velocity

By the similar triangles QTx and PMO,

$$\frac{QT}{Qx} = \frac{PM}{OP} \tag{2}$$

By come sections,

$$\frac{\overline{Qv^2}}{Pv Gv} = \frac{\overline{C}D^2}{CP^2} \tag{3}$$

And from the figure,

$$\frac{Pv}{QS} = \frac{Pv}{Px} = \frac{P\iota}{OP} = \frac{CP}{PF} - \frac{PM}{OP}$$
 (1)

Therefore by (3) and (4) we find

$$\frac{\overline{Qv^2}}{QS \ Gv} = \frac{\overline{CD}^2}{CP \ PF} \quad \frac{PM}{OP}$$
 (5)

In the limit Qx = Qv, and hence (2), (3) and (5) give

$$\frac{Q\overline{T}^2}{QS} = \frac{2C\overline{D}^2}{PF} \quad \binom{PM}{QP}^3 \tag{6}$$

Substituting in (1), we obtain

$$R = \frac{h^2}{OP^2} \frac{PF}{CD^2} \left(\frac{OP}{PM}\right)^3 = \frac{h^2}{a^2h^2} \left(\frac{PF}{PM}\right)^3 OP = \frac{\hbar^2}{a^2b^2} \left(\frac{CY}{OZ}\right)^3 OP, \tag{7}$$

which is the required law of force.

§ 4 Analytical Solution of Bertrand's Problem Based on that Developed by Darboux; Solution of Halphen

The equations of acceleration are,

$$\frac{d^2x}{dt^2} = -R\frac{x}{r} = -R\cos\theta \qquad , \qquad \frac{d^2y}{dt^2} = -R\frac{y}{r} = -k\sin\theta , \qquad (1)$$

where R is the attractive force, at unit distance. Multiplying the first by -y and the second by x, and adding, we get

$$x \frac{d^2 y}{dt^2} - y \frac{d^2 x}{dt^2} = 0 (2)$$

On integrating we obtain

$$x\frac{dy}{dt} - y\frac{dx}{dt} = h ag{3}$$

In polar coordinates this equation becomes

$$r^2 \frac{d\theta}{dt} = h = \text{double areal velocity}$$
, (1)

Let us now put  $u = \frac{1}{i}$ , and then

$$a = \frac{\cos \theta}{u} , \frac{dx}{dt} = -\frac{u \sin \theta + \cos \theta \frac{du}{d\theta}}{u^2} \frac{d\theta}{dt}$$
 (5)

By equation (4) this becomes

$$\frac{dx}{dt} = -h\left(u\sin\theta + \cos\theta \frac{du}{d\bar{\theta}}\right),\tag{6}$$

and 
$$\frac{d^2 x}{dt^2} = -h^2 u^2 \left( u \cos \theta + \cos \theta \frac{d^2 u}{d\theta^2} \right)$$
 (7)

From (7) and (1) we get

$$R = \frac{h^2}{r^2} \left( u + \frac{d^2 u}{d\theta^2} \right), \tag{8}$$

where the centre of force is at the origin

This equation is perfectly general for the determination of R when the equation of the path is known. To get the central force, R, which will cause a particle to describe any given path, we find the value of  $\binom{u+\frac{d^2u}{d\theta^2}}{d\theta^2}$  for that path, and multiply it by  $\frac{h^2}{r^2}$ . Therefore, to find the law of R, when the path is a come section, we have the general equation,

$$ax^{2} + 2bxy + cy^{2} + 2dx + 2fy = q$$
 (1)

Putting  $r = \frac{1}{u}$ , and transforming to polar coordinates, we have

$$\frac{a\cos^2\theta}{u^2} + \frac{2b\sin\theta\cos\theta}{u^2} + \frac{c\sin^2\theta}{u^2} + \frac{2d\cos\theta}{u} + \frac{2f\sin\theta}{u} \qquad q.$$

from which we obtain

$$u = \frac{f \sin \theta + d \cos \theta}{g} + \frac{1}{g} \sqrt{(f^2 + \iota g) \sin^2 \theta + 2(f d + b g) \sin \theta \cos \theta + (d^2 + \iota \iota g) \cos' \theta}$$
 (10)

This equation reduces to the form

$$u = A \sin \theta + B \cos \theta + \sqrt{C \sin 2\theta + D \cos 2\theta + H}, \qquad (11)$$

where

$$A = \frac{f}{g}, \quad B = \frac{d}{g}, \quad C = \frac{fd + bg}{g^2}, \quad D = \frac{d^2 + ag - f^2 - \epsilon g}{2g^2}, \quad H = \frac{d^2 + ag + f^2 + \epsilon g}{2g^2}.$$

From (11) we derive

$$\frac{d^2 u}{d\theta^2} = \frac{-1 \sin \theta - B \cos \theta - C^2 - D^2 - (C \sin 2\theta + D \cos 2\theta)^2 - 2H(C \sin 2\theta + D \cos 2\theta)}{(C \sin 2\theta + D \cos 2\theta + H)^{3/2}}$$
(12)

Therefore by (8) we get

$$R = \frac{h^2}{r^2} \frac{(H^2 - C^2 - D^2)}{(C \sin 2\theta + D \cos 2\theta + H)^{\gamma/2}}$$
 (13)

This is the general expression for R whatever be the constants a, b, c, d, f and g

Since by (11) we have

$$u - A \sin \theta - B \cos \theta = \sqrt{C \sin 2\theta + D \cos 2\theta + H}$$

we may write (13)

$$R = \frac{h^2}{r^2} \frac{(H^2 - C^2 - D^2)}{\left(\frac{1}{r} - A \sin \theta - B \cos \theta\right)^2},$$
(14)

which is another general expression for R

When the come is an ellipse with the origin at the centre, equation (9) takes the form  $ax^2 + cy^2 = ac$ , and from (13) or (14) we find after reduction

$$R = \frac{h^2 r}{ac} \tag{15}$$

The force varies directly as r, which is the well-known law

When the centre of force is on the x-axis between the centre and one of four at a distance m from the centre, equation (9) becomes

$$ax^2 + 2amx + cy^2 = a(c - m^2)$$

and we find from (13)

$$R = \frac{h^2}{r^2} \frac{(a\epsilon)^{1/2}}{\left[(a - c + m^2)\cos^2\theta + \epsilon - m^2\right]^{3/2}}$$
 (16)

Since  $a - c + m^2$  is always negative, the force at unit distance is a maximum in the direction of the apsides and is a minimum when  $\theta = \frac{\pi}{2}$  We have from (14), in this case,

$$R = \frac{h^2 c^2 r}{a \left( c - m^2 - m \alpha \right)^8} \tag{17}$$

This expression can readily be transformed into (16)

When the origin is at one of the foci (13) or (11) gives

$$R = \frac{h^2}{r^2} \frac{e^{1/r}}{a^r},\tag{18}$$

which is the Newtonian law

This is also deducible from (16) by putting m' = e - a

When the centre of force is on the x-axis between one of the foci and the nearest apse, at a distance u from the centre, we obtain from (13)

$$R = \frac{h^2}{r^2 \left[ (u^2 + i^2)^2 \cos^2 \theta + \epsilon - n^2 \right]},$$
 (19)

Since  $a - c + n^2$  is always positive, the force at unit distance is a maximum when  $\theta = \frac{\pi}{2}$ , and a minimum at the apsides. From (11) it is easy to obtain

$$R = h^2 \frac{\epsilon^2}{a} \frac{\epsilon}{(\epsilon - n^2 - n \, \epsilon)^3} \,, \tag{20}$$

which may be transformed into (19).

When the centre of force is on the minor axis at a distance k from the centre, equation (13) gives

$$R = \frac{h^2}{r^2 \left[ (a - \epsilon - \lambda^2) \cos^2 \theta + \epsilon \right]^4}$$
 (21)

Since  $a = c = k^2$  is always negative the force at unit distance is a maximum when  $\theta = 0$ , and a minimum when  $\theta = \frac{\pi}{2}$ . In this case we obtain from (11)

$$R = \frac{a^2}{(a-k^2-ku)^3}$$
 (22)

When the centre of force is within the ellipse, at a distance p from the y-axis, and q from the x-axis, we get from (13)

$$R = \frac{\hbar^2}{r'} \left[ \frac{(ar)^{1/\epsilon}}{2pq \sin \theta \cos \theta + (a - r - q^2 + p') \cos^2 \theta + \epsilon - p'} \right] , \qquad (23)$$

which becomes (19) when q = 0, and (21) when  $\rho = 0$ . We also obtain from (14)

$$R = \frac{h^2 a^2 e^2 r}{(aa - ap^2 - cq^2 - cqy - apa)^3},$$
 (21)

which becomes (20) when q = 0, and (22) when p = 0.

The foregoing values of R are real and positive, and represent all the laws consistent with the observed motions of binary stars

It may be interesting to note that when the centre of force is at one of the apsides of at one end of the minor axis, our general formulae (13) and (14) give indeterminate results. In this case we take the equation of the ellipse with the origin at the end of one of the axes, and calculate R by (8) When the centre of force is at the apse, we obtain after reduction

$$R = \frac{h^2}{L} \frac{\sqrt{\bar{\iota}}}{u \cos^3 \theta} \tag{25}$$

When the centre of force is at the end of the minor axis, we find

$$R = \frac{\hbar^2}{r^2} \frac{\sqrt{a}}{e \sin^3 \theta} \tag{26}$$

In both of these cases the origin is taken in the positive direction from the centre of the ellipse, if the other ends of the axes be chosen the signs of (25) and (26) will be reversed

When c = a in (25) or (26) the conic becomes a circle, and the expression reduces to the well-known law

$$R = \frac{8h^2a^{6/2}}{r^5} \tag{27}$$

The expression for the force at external points may be derived in a manner entirely similar to that for points within

#### Solution of Halphen\*

Let m be the mass of the central body, and R an unknown function of x and y. Then we have the equations

$$m \frac{d^2x}{dt^2} = -R \frac{x}{r}$$
 ,  $m \frac{d^2y}{dt^2} = -R \frac{y}{r}$  (28)

R is to be determined by the condition that the orbit of the particle is a conic section. Let

$$\frac{dx}{dt} = x' \quad , \quad \frac{dy}{dt} = y' \quad , \quad R = -mur \,, \tag{29}$$

where u is an unknown function of x and y

<sup>\*</sup> TISSERAND'S Mécanique Celeste, Tome I, Cap I, where the original solution has been somewhat modified

From (28) and (29) we obtain

$$\frac{dx'}{dt} = ux \quad , \quad \frac{dy'}{dt} = uy \tag{30}$$

By this equation we have

$$\frac{d}{dt}F(x,y,x',y') = x'\frac{\partial F}{\partial x} + y'\frac{\partial F}{\partial y} + u\left(x\frac{\partial F}{\partial x'} + y\frac{\partial F}{\partial y'}\right)$$
(31)

We now proceed to find the differential equation which is common to all comes. The general equation of a come has the form,

$$Ax^{2} + 2Bxy + Cy^{2} + 2Fx + 2Gy + H = 0, (32)$$

in which there are five arbitrary constants. Taking x as the independent variable and differentiating five times in succession we have, in Lagrange's notation,

We now have to eliminate the five constants in (32) and (33). We notice that the last three equations of (33) are homogeneous, containing only the three constants C, B and G, and we can eliminate them by equating to zero the determinant

$$\Delta = \begin{vmatrix} yy''' + 3y'y'' & xy''' + 3y'' & y''' \\ yy^{v} + 4y'y''' + 3y''^{2} & xy^{v} + 4y''' & y^{v} \\ yy^{v} + 5y'y^{v} + 10y''y''' & xy^{v} + 5y^{v} & y^{v} \end{vmatrix}$$
(31)

By elementary principles of Determinants equation (34) reduces to

$$\Delta = \begin{bmatrix} 0 & 3i'' & i''' \\ 3i'' & 4i''' & i^{N} \\ 10i''' & 5i'^{N} & i^{N} \end{bmatrix}$$
(35)

Expanding (35) and returning to the differential notation, we have

$$9\left(\frac{d^{2}y}{dx^{2}}\right)^{2}\frac{d^{5}y}{dx^{5}} - 45\frac{d^{2}y}{dx^{2}}\frac{d^{3}y}{dx^{3}}\frac{d^{4}y}{dx^{4}} + 40\left(\frac{d^{3}y}{d^{3}y}\right)^{8} = 0$$
(36)

This is the general differential equation of a conic section We now calculate  $\frac{d^2y}{dx^2}$   $\frac{d^5y}{dx^5}$  from the relations expressed in (29), (30) and (31) We have

$$\frac{dy}{dx} = \frac{y'}{x'},$$

therefore

 $u'\frac{d^2y}{du^2} = \frac{u'uy - y'uu}{a'^2},$ 

or

$$v'^{3} \frac{d^{2}y}{dJ^{2}} = (\iota'y - y'\iota)u \tag{37}$$

Since the force is central, by the law of areas, (x'y - y'x) is constant. Therefore we derive

$$x^{15} \frac{d^{3}y}{dx^{3}} = (x^{i}y - y^{i}x) \left( x^{i} \frac{du}{dt} - 3u^{2}x \right)$$

$$x^{17} \frac{d^{4}y}{dx^{4}} = (x^{i}y - y^{i}x) \left( x^{12} \frac{d^{2}u}{dt^{2}} - 10uxx^{i} \frac{du}{dt} - 3u^{2}x^{12} + 15u^{8}x^{2} \right)$$

$$x^{19} \frac{d^{5}y}{dx^{5}} = (x^{i}y - y^{i}x) \left[ x^{13} \frac{d^{3}u}{dt^{3}} - 15uxx^{12} \frac{d^{2}u}{dt^{2}} - 10xx^{12} \left( \frac{du}{dt} \right)^{2} + \frac{du}{dt} \left( 105u^{2}x^{2}x^{i} - 16ux^{13} \right) + 45u^{3}x^{3}x^{2} - 105u^{4}x^{3} \right]$$

$$(38)$$

Substituting these values in (36) and reducing, we obtain

$$9u^{2}\frac{d^{3}u}{dt^{3}} - 45\frac{du}{dt}\frac{d^{2}u}{dt^{2}} + 40\left(\frac{du}{dt}\right)^{3} = 9u^{3}\frac{du}{dt}$$

$$(39)$$

Putting  $u = w^{-w_2}$ , in which w is a function of x and y, (39) reduces to

$$\frac{d^8w}{dt^8} = w^{-8/2} \frac{dw}{dt} \tag{40}$$

When we remember that

$$\frac{dv'}{dt} = vw^{-3/2} \text{ and } \frac{dy'}{dt} = yw^{-3/2},$$

and that w is a function of x and y, we get

$$\frac{dw}{dt} = v' \frac{\partial w}{\partial x} + y' \frac{\partial w}{\partial y}$$

$$\frac{d^3w}{dt^3} = x'^{18} \frac{\partial^8w}{\partial x^8} + 3x'^{2}y' \frac{\partial^8w}{\partial x^{2}\partial y} + 3x'y'^{2} \frac{\partial^3w}{\partial x^{2}\partial y^{2}} + y'^{3} \frac{\partial^3w}{\partial y^{3}}$$

$$+ w^{-3/2} \left( x' \frac{\partial w}{\partial x} + y' \frac{\partial w}{\partial y} \right) + 3w^{-3/2} \left( x'y + y'x \right) \frac{\partial^2w}{\partial x \partial y}$$

$$+ 3w^{-3/2} \left( xx' \frac{\partial^2w}{\partial x^2} + yy' \frac{\partial^2w}{\partial y^2} \right)$$

$$- \frac{3}{4} w^{-5/2} \left( x \frac{\partial w}{\partial x} + y \frac{\partial w}{\partial y} \right) \left( x' \frac{\partial w}{\partial x} + y' \frac{\partial w}{\partial y} \right)$$
(41)

Substituting these values in (40), we obtain

$$0 = i^{13} \frac{\partial^{3} w}{\partial x^{3}} + 3i^{12} y^{l} \frac{\partial^{3} w}{\partial x^{2} \partial y} + 3i^{l} y^{l^{2}} \frac{\partial^{3} w}{\partial x \partial y^{2}} + y^{l^{3}} \frac{\partial^{3} w}{\partial y^{3}}$$

$$+ \frac{3}{2} i^{l} w^{-5/2} \left[ 2w \left( i \frac{\partial^{2} w}{\partial x^{2}} + y \frac{\partial^{2} w}{\partial x \partial y} \right) - \frac{\partial u}{\partial i} \left( i \frac{\partial w}{\partial x} + y \frac{\partial w}{\partial y} \right) \right]$$

$$+ \frac{3}{2} y^{l} w^{-5/2} \left[ 2w \left( y \frac{\partial^{2} w}{\partial y^{2}} + x \frac{\partial^{2} w}{\partial x \partial y} \right) - \frac{\partial u}{\partial y} \left( i \frac{\partial w}{\partial x} + y \frac{\partial w}{\partial y} \right) \right]$$

$$(42)$$

This equation holds true whatever be the value of t, and hence when t = 0, in which case x, y, x', y' may be any four quantities mutually independent of one another. Then (42) gives the following equations

$$\frac{\partial^3 w}{\partial x^3} = 0 , \quad \frac{\partial^3 w}{\partial x^2 \partial y} = 0 , \quad \frac{\partial^3 w}{\partial x \partial y^2} = 0 , \quad \frac{\partial^3 w}{\partial y^3} = 0$$
 (43)

$$2w\left(x\frac{\partial^{2}w}{\partial x^{2}} + y\frac{\partial^{2}w}{\partial x\partial y}\right) - \frac{\partial w}{\partial x}\left(x\frac{\partial w}{\partial x} + y\frac{\partial w}{\partial y}\right) = 0$$

$$2w\left(y\frac{\partial^{2}w}{\partial y^{2}} + x\frac{\partial^{2}w}{\partial x\partial y}\right) - \frac{\partial w}{\partial y}\left(x\frac{\partial w}{\partial x} + y\frac{\partial w}{\partial y}\right) = 0$$

$$(14)$$

We obtain from (43), when we denote the arbitrary constants by a, b,  $\epsilon$ , f, g, h,  $w = a \iota^2 + 2b \iota y + \epsilon y^2 + 2f \iota + 2g y + h \tag{15}$ 

Forming the differentials and substituting in (44), we obtain

$$\begin{cases} (hf - aq) \, i \, y + (ef - bq) \, y^2 + (f^2 - ah) \, i + (fq - bh) \, y = 0 \\ (bq - ef) \, a \, y + (aq - bf) \, a^2 + (fq - bh) \, i + (q^2 - eh) \, y = 0 \end{cases}$$

$$\begin{cases} (46)$$

Since these equations hold true for all values of x and y, we find

$$ay - bf = 0 \quad , \quad by - cf = 0 \tag{47}$$

$$f^2 - ah = 0$$
 ,  $g^2 - ch = 0$  ,  $fg - bh = 0$  (48)

From (48) we have

$$fh(ag - bf) = 0 \quad , \quad gh(bg - cf) = 0 \tag{49}$$

Then, if none of the quantities f, g, h vanishes, (47) follows from (48), and it is sufficient to verify the latter

We may write (45) in the form

$$w = \frac{1}{h} \left[ (fx + gy + h)^2 - (f^2 - ah) a^2 - (g^2 - ch) y^2 - 2(fy - bh) xy \right], \tag{50}$$

which, in consequence of (48), becomes

$$w = \frac{(fr + gy + h)^2}{h} \tag{51}$$

Therefore, since  $u = w^{-3/2}$ , we have by (29)

$$R_1 = m h^{3/2} \frac{r}{(f \iota + g g + h)^3}, \tag{52}$$

which is an expression for the force sought. When h = 0, (48) leads to f = 0 and g = 0. In this case we have

$$w = ar^2 + 2bry + cy^2, (53)$$

from which we get

$$R_2 = m \frac{i}{(\bar{a}\,\bar{i}^2 + 2b\,i\,y + \epsilon\,y^2)^{3/2}} \tag{54}$$

This is another expression for the force, whatever be the constants a, b and c. When f = 0, (47) and (48) give ay = by = ah = bh = 0,  $y^2 = ch$ , from which a = b

In this case we get from (50)

$$w = \frac{(qy+h)^2}{h}, (55)$$

which gives the same result as (52), when f = 0

Thus there are two laws of force, and only two, which answer the question, but the forces  $R_1$  and  $R_2$  contain both the radius vector r, and the polar angle

$$\theta = \tan^{-1} \frac{y}{x}$$

If the forces depend upon r alone, as is natural to suppose, we should have in  $R_1$ , f = g = 0; and in  $R_2$ , a = c and b = 0 Then we find

$$R_1 = mr$$
 ,  $R_2 = \frac{m}{r^2}$  (56)

The first of these laws is excluded by observation, the second is the law of Newtonian gravitation.

§ 5 Theory of the Determination, by Means of a Single Spectroscopic Observation, of the Absolute Dimensions, Parallaxes and Masses of Stellar Systems whose Orbits are Known from Micrometrical Measurement\*

Recent researches on the orbits of double stars have led me to develop the suggestion, first thrown out by Fox Talbot in 1871† and since somewhat varied by others,‡ for determining the absolute dimensions, parallaxes and masses of stellar systems by spectroscopic observation of the relative motion of the companion in the line of sight. A simple and general theory of this motion may be derived from the application of the hodograph of the ellipse, and hence we shall now investigate the nature of this curve

Let x, y be the coordinates of a point in the ellipse, x' y' those of the corresponding point in the hodograph, then we shall have

$$x' = \frac{\mathrm{d}x}{\mathrm{d}t}$$
 ,  $y' = \frac{\mathrm{d}y}{\mathrm{d}t}$  (1)

Suppose M to be attracting the mass in the focus of the ellipse, and let r and  $\theta$  be the polar coordinates of the particle moving in the orbit, and we have

$$\frac{\mathrm{d}^2 \nu}{\mathrm{d}t^2} = -\frac{Mr}{r^3} = -\frac{M}{r^2} \cos\theta \quad , \quad \frac{\mathrm{d}^2 y}{\mathrm{d}t^2} = -\frac{My}{r^3} = -\frac{M}{r^2} \sin\theta \tag{2}$$

By the principle of the conservation of areas resulting from central forces, we have the equation

$$r^2 \frac{\mathrm{d}\theta}{\mathrm{d}t} = \text{double areal velocity} = C$$
,

 $\mathbf{or}$ 

$$r^2 = C \frac{\mathrm{d}t}{\mathrm{d}\theta},$$

and hence

$$\frac{\mathrm{d}^2 x}{\mathrm{d}t^2} = -\frac{M}{C}\cos\theta \,\frac{\mathrm{d}\theta}{\mathrm{d}t} \quad , \quad \frac{\mathrm{d}^2 y}{\mathrm{d}t^2} = -\frac{M}{C}\sin\theta \,\frac{\mathrm{d}\theta}{\mathrm{d}t} \tag{3}$$

If we integrate we obtain

$$\frac{\mathrm{d}a}{\mathrm{d}t} + a = -\frac{M}{C}\sin\theta \quad , \quad \frac{\mathrm{d}y}{\mathrm{d}t} + b = +\frac{M}{C}\cos\theta \,, \tag{4}$$

<sup>\*</sup>Astronomische Nachrichten, No 3314

<sup>†</sup> Report of British Association, 1871, Part II p 34, CLERKE's "System of the Stars," p 201, and "History of Astronomy during the 19th Century," third edition, p 467

<sup>‡</sup>Rambaur, M N, March, 1890, Wilsing, A N, 3198, also a paper on the determination of orbits from spectroscopic observation of the velocity-components in the line of sight, by Lehman-Fii hús, A N, 3242

where a and b are the arbitrary constants of integration. But since

$$\sin\theta = \frac{y}{2}$$
 ,  $\cos\theta = \frac{y}{2}$  ,

we find

$$\frac{\mathrm{d}x}{\mathrm{d}t} + a = -\frac{M}{C}\frac{y}{r} \quad , \quad \frac{\mathrm{d}y}{\mathrm{d}t} + b = +\frac{M}{C}\frac{i}{r} \tag{5}$$

By means of equation (1) we have

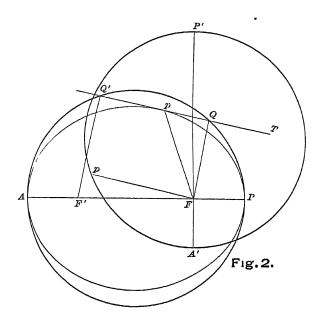

$$x' + a = -\frac{M}{C} \frac{y}{r}$$
 ,  $y' + b = +\frac{M}{C} \frac{i}{i}$  ,

and on squaring and adding we obtain

$$(a'+a)^2 + (y'+b)^2 = \frac{M^2}{C^2}, (6)$$

which shows that the hodograph of the ellipse is a circle of radius  $\frac{M}{C}$ 

The following geometrical proof will render the application somewhat more intelligible

In the figure let PpA be the ellipse described by the particle p, PA being the major axis, and F and F' the two foci. Let pT be the tangent to the ellipse at p, and let the perpendicular from the focus upon the tangent be denoted by FQ. Then by definition the radius vector of the point in the hodograph is parallel to the tangent pT and proportional to the velocity at

the point p It is well known from the law of the conservation of areas that this velocity is always inversely as the perpendicular FQ, or directly proportional to the length of F'Q'. But the locus of Q or Q' is known to be the auxiliary circle described upon the major axis as a diameter. Therefore we see that the hodograph is of the same form as the locus of Q', but since the point p' in the hodograph is on a radius vector parallel to pT, its situation relative to the focus F will always be 90° in advance of Q

The shape and situation of the hodograph relative to the ellipse is shown in the figure. Thus, when p is in periastron the point of the hodograph is in the direction perpendicular to the major axis, and at a distance proportional to F'Q', which is then equal to F'P, and similarly for other points of the orbit. For the sake of clearness we have made the hodograph in the figure of the same size as the auxiliary circle of the ellipse, but if the radius vector in the hodograph is to represent the velocity in the ellipse the scale of the hodograph ought in reality to be greatly reduced

If the orbit of a double star is given we may at once construct the form of the hodograph, the position relative to the ellipse being the same as in the preceding figure. Moreover if the velocity of the companion about the central star is known in absolute units for any point of the orbit, we may determine the velocity for any other point by means of the hodograph. For the magnitude of the velocity will be the length of the radius vector of the hodograph which is parallel to the tangent of the orbit at the point in question, and can easily be computed or measured graphically directly from the diagram

When the elements of a binary are known, we may determine the component of the velocity in the line of sight as follows. Suppose  $\rho$  to be the radius vector of the point in the hodograph, and  $\omega$  to be the angle made by the radius vector  $\rho$  with the ascending node, and therefore identical with the angle made by the tangent to the orbit with the line of nodes, and let i be the inclination of the plane of the orbit to the plane tangent to the celestial sphere. Then we evidently have, as the component towards the earth,

$$\kappa = \rho \sin \omega \sin \iota \tag{7}$$

The angle  $\imath$  is an element of the star's orbit and is known, the angle  $\omega$  can be computed from the theory of the ellipse, or can be determined directly from the diagram; and when  $\rho$  is known in absolute units the component in the line of sight is perfectly determined.

We shall now show how to compute  $\omega$  and  $\rho$  for any given orbit. The

radius vector of the star r and the true anomaly v must be computed by the usual process, and then we find the radius vector with respect to the other focus

$$r' = 2a - r,$$

and we have the angle  $\gamma$  by means of the equation

$$\sin \gamma = \frac{\tau \sin \nu}{\tau'} \tag{8}$$

The angle  $\psi$  between the radu vectores drawn to the two foci is evidently equal to  $v - \gamma$ , and hence

$$\frac{\psi}{2} = \frac{v - \gamma}{2} \tag{9}$$

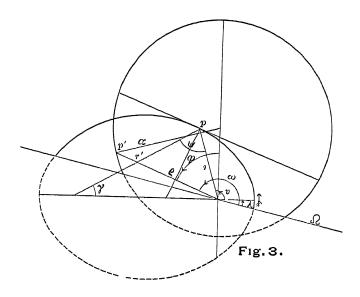

It is also easy to see that  $\varphi$ , the angle made by the tangent with the latus rectum of the ellipse, is given by

$$\varphi = r - \frac{1}{2}\psi \tag{10}$$

When the value of g is determined, it is clear that

$$\omega = \lambda + 90^{\circ} + \varphi = v + \lambda + 90^{\circ} - \frac{1}{2}\psi, \qquad (11)$$

so that we easily find the angle of the radius vector  $\rho$  from the ascending node

We may compute the length of this radius vector in the hodograph in the following manner. Let the radius of the circle be denoted by a, its value being

supposed known in absolute units, the linear eccentricity will be  $\alpha e$ , and we shall have

$$\alpha^2 = \rho^2 + \alpha^2 e^2 - 2\rho \alpha e \cos \varphi ,$$

on solving for  $\rho$  we find

$$\rho = \alpha \left[ e \cos \varphi + \sqrt{1 - e^2 \sin^2 \varphi} \right] \tag{12}$$

Thus when  $\alpha$ , the radius of the hodograph, is known in absolute units, we are enabled by means of (11) and (12) to predict the motion in the line of sight for any instant whatever

Now suppose we determine the relative motion of the companion in the line of sight by means of a modern Spectrograph such as that at Potsdam, this will give us results freed from the effect of the proper motion of the system in space, as well as the secular motion of the sun and the orbital motion of the earth. Then by equation (7) we have

$$\rho = \frac{\kappa}{\sin \omega \sin \nu},\tag{1.3}$$

in which  $\kappa$  is furnished by spectroscopic measurement, and  $\omega$  and  $\imath$  are found from the orbit deduced from micrometrical measures.

A single observation therefore gives us the absolute velocity in the orbit, and this fixes the scale of the hodograph. For since we have

$$\rho = \alpha \left[ e \cos \varphi + \sqrt{1 - e^2 \sin^2 \varphi} \right],$$

and e and  $\varphi$  are known, we may determine the radius of the hodograph by

$$\alpha = \frac{\rho}{\left[e\cos\varphi + \sqrt{1 - e^2\sin^2\varphi}\right]} \tag{14}$$

Having determined  $\kappa$  by observation, we get the absolute value of  $\rho$  by (13) and of  $\alpha$  by (14), and we may then predict the value of  $\kappa$  in absolute units for any time whatever. In practice it will be desirable to measure the motion in the line of sight when the function  $\kappa$  is a maximum, in order that an error in  $\kappa$  may have a minimum effect upon the radius of the hodograph

When  $\alpha$  is thus determined in absolute units, the problem arises to find the absolute dimensions of the system, the masses of the stars, and their distance from the earth. Suppose we choose two epochs separated by a convenient interval of time, say a year or a fractional part of a year, when the companion is near apastron, and the velocity changes slowly. We shall denote the radii vectores by  $r_1$  and  $r_2$ , and the interval of time by  $t_2-t_1$ . The length of the included elliptic arc can be expressed rigorously only by means of an elliptic

integral, but as the evaluation of this integral would be inconvenient in practice and for a short are unnecessarily exact, we shall determine the length of the arc by mechanical quadrature. Thus we have

arc = 
$$\int_{t_1}^{t_2} \rho \, dt = \overline{\rho} (t_2 - t_1)$$
,

where  $\overline{\rho}$  is the average velocity of the interval, easily deduced from the hodograph. If the interval is short compared to the time of revolution, so that the arc may be put equal to its sine, we shall have approximately

$$\frac{r_1 + r_2}{2} \sin (r_2 - r_1) = \overline{\rho} (t_2 - t_1) ,$$

or

$$i_1 + i_2 = \frac{2\bar{\rho} (t_2 - t_1)}{\sin(v_1 - v_1)}$$

Now  $v_2$  and  $v_1$  are known true anomalies, and  $r_1$  and  $r_2$  are given in units of the major axis by the polar equation

$$\frac{r}{a} = \frac{(1-e^2)}{1+e\cos u}$$

Hence, with  $r_1$  and  $r_2$  thus expressed numerically, we find

$$a = \frac{2\overline{\rho}(t_2 - t_1)}{(r_1 + r_2) \sin(v_2 - v_1)} \tag{15}$$

Here the interval  $t_2-t_1$  must be expressed in the same units as  $\bar{\rho}$ , preferably in kilometres per second. The length of the major semi-axis of the orbit is thus found in kilometres, and the absolute dimensions of the system are determined.

The parallax of the system is equal to the major semi-axis of the orbit in seconds of are divided by the major semi-axis in astronomical units; or the distance of the system from the earth is equal to the major semi-axis in astronomical units divided by the sine of the angle subtended by the major semi-axis in seconds of arc; thus

$$\Delta = \frac{a}{\sin a''} \tag{16}$$

If  $M_1 + M_2$  denote the combined mass of the system, M + m the combined mass of the sun and earth, a the major semi-axis of the orbit of the companion, and P the period of revolution, R the distance of the earth from the sun, and

T the length of the sidereal year, we have, by the well known extension of Kepler's law

$$M_1 + M_2 = \frac{a^3}{R^8} \frac{T^2}{P^2} (M + m)$$
 (17)

If as usual we put M+m=1, R=1, and T=1, and express a and P in these units, we find

$$M_1 + M_2 = \frac{a^8}{P^2}, (18)$$

where the mass of the system will be expressed in units of the combined mass of the sun and earth. The mass of the system is thus determined absolutely

In conclusion it seems proper to add that this investigation was stimulated by an elegant proof of Mr. F R Moulton, that the aberrational orbit of a fixed star is the hodograph of the ellipse in which the earth moves, and therefore a circle. The idea brought out in Mr Moulton's proof caused me to revert to the motion of binaries in the line of sight, and hence no small part of the credit is due to him for the interesting application of Sir W. R Hamilton's hodograph given above

#### § 6 Rigorous Method for Testing the Universality of the Law of Gravitation\*

It remains to consider how we may use the foregoing results to test the law of Newton. It is evident that the law of gravitation can be tested by comparing the observed with the theoretical motion of the companion in the line of sight. We may choose a system whose orbit is accurately known and whose stars are suitable for exact spectroscopic measurement of the component  $\kappa$ ; we then determine from one or more observations at a suitable epoch the absolute dimensions of the orbit, as explained in the preceding theory, and predict the motion in the line of sight for other parts of the orbit, perhaps for a whole revolution. If we then determine by spectroscopic measurement the value of the component  $\kappa$  independent of any theory, and find that the theoretical results are confirmed by actual observations, we may consider the result a direct observational proof that the force which retains the companion in its orbit is Newtonian gravitation

For we know from micrometrical measures that the areas described by the radius vector of the companion are proportional to the time, and therefore that

<sup>\*</sup>Astronomische Nachrichten No 3314

the force is central, and the observations of 42 Comae Berenuces, whose motion happens to be in the plane of vision, indicate that the orbit is a plane curve. The motion being in a plane and the force being central, we must be able to show that the principal star is in the focus of the real ellipse. This can be done if we can show by spectroscopic observations that the inclination and node resulting from the theory of gravitation account perfectly for the motion in the line of sight.

We therefore assume the law of gravitation in deriving the elements of the orbit and in predicting the motion in the line of sight, as heretofore explained; spectroscopic observation will enable us to test the results of theory experimentally. If the theoretical results are confirmed by observation throughout a revolution — thus showing that the node and inclination are identical with those resulting from the theory of gravitation — we may regard the observations as giving a direct and incontestible proof of the validity of the law of Newton in the stellar systems

If we desire to ascertain whether any other inclination and node — in other words, any other law of force — could give rise at every point of the orbit to a relative motion in the line of sight identical with that resulting from the law of gravitation, we may proceed as follows. Suppose that some other inclination and node and orbital velocity be possible; they will differ by unknown quantities from those values resulting from the theory of gravitation, and we shall have the relation

$$\rho \sin \iota \sin \omega = \rho' \sin (\iota + \gamma) \sin (\omega + \delta)$$

By expanding and reducing we find

$$\rho \; = \; \rho' \; \{\cos\gamma \; \cos\delta + \cos\gamma \; \cot\omega \; \sin\delta + \sin\gamma \; \cot\iota \; \cos\delta + \sin\gamma \; \sin\delta \; \cot\iota \; \cot\omega \}$$

But we observe that  $\omega$  is a variable angle depending on the position of the body in the oibit; and since  $\omega=0$ , or  $\omega=\pi$  would render the cotangent infinite, and  $\rho$  is known to be finite for every point, (the two bodies never come into contact but are always separated by a certain distance), it follows that those terms depending on cot  $\omega$  must vanish, or  $\delta=0$ , and the line of nodes becomes the same as that resulting from the theory of gravitation. Our expression thus takes the form

$$\rho = \rho'(\cos \gamma + \sin \gamma \cot i) = \rho' K,$$

where K is a constant

Therefore, if the inclination differs by  $\gamma$  from the value given by the theory of gravitation, it will follow that the velocity at every point of the real orbit

must be multiplied by a constant factor. But since no alteration of the inclination can change the radius vector at the line of nodes, it follows that at these points the orbital velocities would necessarily be the same however the inclination might vary. And since we have seen that the line of nodes is identical with that given by the theory of gravitation, we conclude that the velocities in the orbits could not differ throughout by a constant ratio. Hence it is evident that  $\cos \gamma + \sin \gamma \cot \iota = 1$ , or  $\gamma = 0$ , and the inclination is identical with that resulting from the theory of gravitation. It follows therefore that no other conceivable law of attraction could produce the same relative motion in the line of sight as the law of inverse squares. Consequently if observation shall give for every point a relative motion in the line of sight which accords with theory, we may confidently conclude that Newtonian gravitation is the force which retains the stars in their orbits.

#### § 7. On the Theoretical Possibility of Determining the Distances of Star-Clusters and of the Milky Way, and of Investigating the Structure of the Heavens by Actual Measurement\*

The practical problem of measuring the parallaxes of the fixed stars is one of the greatest of modern Astronomy, and has been solved heretofore very imperfectly. The quantity to be deduced is so very small that accidental and systematic errors often wholly obscure the element desired, and render the probable errors of most of our parallaxes painfully large compared to the minute quantities sought. Moreover, the method of relative parallax, which is the only one in general use, aside from its theoretical inaccuracy, is encumbered with many practical difficulties, the chief of which is in finding suitable comparison stars; and hence not a few astronomers have practically abandoned hope of determining the distances of the fixed stars with any considerable degree of None have felt these difficulties more keenly than those astronomers who have attempted investigations requiring exact knowledge of the masses and dimensions of the stellar systems. At the present time the only parallaxes of binaries which lay claim to any considerable precision are those of a Centauri (0" 75), a Canis Majoris (0" 38), 70 Ophiuchi (0" 162), and  $\eta$  Cassiopeur To this list we might perhaps add a few spectroscopic binaries whose parallaxes have been investigated, but even then the number of systems

<sup>\*</sup>Astronomische Nachrichten, No 3323

would remain very small, and altogether insufficient to support any sound generalization respecting the masses and dimensions of binary stars as a class.

If we consider single, instead of double stars, it will be evident that while a much larger number have been measured for parallax, and in a good many cases reliable values have been derived, yet in the majority of instances the divergence of results obtained by different observers, may fairly be taken to indicate that our knowledge of stellar parallax is still very limited; and owing to the small dimensions of the earth's orbit, very little hope has been entertained of material improvement in time to come.

The method which we have developed in section 5 is full of promise for the case of binary stars. This method is theoretically applicable to any pair where the components have an angular separation of 0"1, and a single application of the spectrograph at a suitable epoch gives us the absolute dimensions, mass and parallax of the system

As 0"1 is about the present limit of exact micrometrical or heliometrical measurement, and as this angle would correspond to the parallax of a fixed star at the distance of 36 light-years (eight times the distance of a Centauri) we see that all smaller parallaxes determined by methods heretofore in use must necessarily remain very uncertain. On the other hand the spectroscopic method will apply satisfactorily to much more distant systems—to pairs which have an angular separation of 0"1, and where an observer by the ordinary method would find that our sun had a parallax of this amount. This is equivalent to using the major semi-axis of the stellar orbit for a base line instead of the mean distance of the earth from the sun; and thus the parallaxes deduced by the spectroscopic method might be as much smaller than 0".1 as the major axis of the stellar orbit is larger than that of the earth, provided of course that the combined mass of the stars is great enough to give a relative motion of the companion in the line of sight which can be measured with the desired precision.

Thus, by the usual method the parallax of a Centauri would be just measurable at the distance of 36 light-years, and would amount to 0"1, and as the major semi-axis of the orbit would there subtend an angle of 2"2, the spectroscopic method could be applied at 22 times that distance, or when the system is removed from us by about 800 light-years. Of course we can never hope to measure the distance of a system so remote by the ordinary method, since at the distance of 800 light-years the parallax would amount to only 0".0045 If the mass and dimensions of the system be larger than those of a Centauri, the spectroscopic method would enable us to measure a parallax correspondingly

smaller. While at present little is known of the magnitude of binary systems, it seems probable that in some cases at least the masses and dimensions will much surpass those of a Centauri. It is therefore probable that it will occasionally be possible to determine the distances of systems removed from us by several thousand light-years

The present state of Astronomy does not permit us to make a confident assertion with regard to the distances of the clusters or of the Milky Way, but it seems exceedingly probable that both are very remote. In each of these species of stellar aggregation there exists a considerable but unknown number of binary stars which can be detected with our present optical means Burnham has searched for double stars in several of the great northern clusters, such as Praesepe, the Plerades and the great clusters in Perseus, Hercules, &c (Publications of Lick Obs, vol II pp 211-216), and discovered a number of pans which promise to be physically connected He observes that interesting stars are apparently more frequent in wide clusters like the Pleiades, Praesepe, and the great cluster in Perseus, than in the more compact clusters like that Yet he has discovered an important pair in this dense globular in Hercules cluster, and Sir John Herschel has likewise detected double stars of special interest in several of the great clusters of the southern hemisphere. It is not to be doubted that many more such objects will be detected when the clusters generally are critically examined under the powers of our great modern refractors

When the orbits of these binaries have been found by exact micrometrical measurement, the spectroscopic method will eventually afford the means for determining their immense distances, not by probable assumptions but by exact computation. It is evident therefore that if we are ever to determine the distances of clusters from the earth—and no sound ideas of the nature of these masses of stars can be formed until such determination is made—we must first search the clusters critically for binary stars, and determine their orbits by micrometrical measurement. If, when the orbit is known, it shall appear that the binary has the same proper motion as the adjacent stars of the group, there will be a strong presumption that the system forms a part of the cluster. If the pair be also of about the same magnitude as its neighbors, and of the same color and spectral type, we may conclude with practical certainty that the binary is intimately connected with the mass of stars in which it is projected

Determination of the parallax of the binary will therefore give the distance of the cluster from the earth, and supply all desired information as to the dimensions of the cluster, the brilliancy of its stars, their mutual distances, &c. If in like manner any group of stars in the Milky Way could be carefully

searched for binary systems, and some intimate connection of a pair with neighboring stars shown to exist, a determination of its orbit and an application of the spectroscopic method would lead to a knowledge of the distance of that part of the Milky Way By extending the same process to all parts of the Galaxy it will be possible in the course of time to ascertain the nature of that immense aggregation of stars, and throw light upon the construction of the heavens. While the spectroscopic method applies only to binary stars, it is evident that their great abundance and universal distribution in space will some day give a means for determining with precision and certainty the actual structure of the sidereal universe.

We must not expect that the immense possibilities here outlined will be practically realized at once, or even in the near future, yet giant refractors like the 40-inch Yerkes Telescope will give such power for separating close double stars and for supplying a great amount of light for the spectroscopic study of faint objects, that an application of these ideas may not be found impossible in the course of the coming century. If there be spectroscopic or photographic difficulties, the progress of spectroscopic Astronomy during the last thirty years justifies the belief that such obstacles will not continue to be insurmountable. The great philosophic interest attaching to the foregoing method for investigating the structure of the visible universe by exact spectroscopic measurement, instead of by the doubtful processes of gauging employed by Herschel and Struve, appears to be a sufficient justification for considering what is at present only a theoretical possibility. The history of Astronomy shows that it is not always the theories that can be realized in a decade or even in a century which in the long run exercise the most important influence on the development of science.

## § 8. Historical Sketch of the Different Methods for Determining Orbits of Double Stars

It is assumed that the law of gravitation governs the motions of double stars, and therefore that the orbits are ellipses with the principal stars in the foci. From the nature of come sections the centre of the real ellipse will be projected into the centre of the apparent ellipse. But in general the foci of the real ellipse will not fall upon the foci of the apparent ellipse. If, however, a line be drawn from the centre of the apparent ellipse to the principal star and prolonged in either direction until it intersects the curve, the result will define the projection of the real major axis. The diameter of the

ellipse conjugate to this line will be the projection of the minor axis. Thus It is easy to fix the positions of the real major and minor axes as seen in the apparent orbit. Since all parts of the major axis are shortened in the same ratio, the eccentricity of the real orbit may be deduced from the apparent orbit, by dividing the distance from the centre to the principal star by the major semi-axis as seen in projection. The end of this axis which is nearest the principal star will be the periastron, that faithest away, the apastron, the dates corresponding to the passage of the companion through these points will give the epochs of periastron and apastron passage respectively. It is evident that only one diameter of the real ellipse will suffer no shortening, owing to projection, and this is the diameter parallel to the line of nodes. If from points on the apparent ellipse perpendiculars be drawn to this diameter, and then increased in the ratio of cosi to 1, we shall get points of the real orbit whose projections give points on the apparent orbit.

The observations of a double star are expressed in polar coordinates,  $\rho$  and  $\theta$ , which give the angular separation of the components in seconds of the aic of a great circle, and the position-angle of the companion with respect to The companion is thus referred to the principal star regarded as fixed, and hence the observations give the means of finding only the relative orbit of one star about the other. The absolute orbit of either star about the centre of gravity of the system has a form similar to that of the relative orbit, but the linear dimensions are reduced in the ratio of  $M_2$  or  $M_1$  to  $M_1 + M_2$ , where  $M_1$  and  $M_2$  are the masses of the stars. The absolute orbits of the stars have the same shape, but are reversed in relative position The centre of gravity of a pair of stars can be determined only by the criterion that the centre of gravity of a system moves uniformly in a right line, and as most of the systems have too little motion to define this point with any considerable degree of precision, owing to the imperfect state of our absolute positions as determined by the meridian circle, it is in general impossible to define the absolute orbits or relative masses of the stars With few exceptions, therefore, astronomers have contented themselves heretofore with determining the relative orbit of one body about the other

The first method for determining the orbit of a double star was proposed by Savary in 1827 (Connaissance des Temps, 1830) This method is closely analogous to those used for planets and comets, in so far as it rests on the treatment of four complete observations for the definition of the seven elements. The problem is solved by elaborate geometrical constructions, such as characterize work in pure mathematics rather than the practical processes which must

be invoked by the working computer Savary's principal equation is based on the difference between the sector and triangle, the area derived from the time being equated with an expression involving the products of the semi-axes and eccentric angles of the apparent ellipse. The method is thus ill adapted to the determination of an orbit from such positions as are furnished by the measures of double stars.

Encke recast the method of Savary, from the point of view of a practical computer, and deduced formulae similar to those used by astronomers in their work on planets and comets. Rejecting the equations depending on conjugate diameters, so much employed by the French geometer, he based his formulae on recognized astronomical processes and developed tables to facilitate their application. As Savary had applied his method to  $\xi$  Ursae Majoris, Encke was led to illustrate his computations on the equally well-known system of 70 Ophiuchi (Berliner Astronomisches Jahrbuch, 1832).

SIR JOHN HERSCHEL took up the problem about 1830, and sought to improve the processes by a graphical method which enabled him to make use of all the observational material, and to eliminate the grosser errors of the individual observations. He was convinced that in order to obtain orbits of a satisfactory character, it would be necessary to correct the angles by an interpolating curve, one axis representing the time, the other the angle, and that the distances must be rejected altogether, except for the determination of the major axis. He proceeds by successive approximations to deduce normal places for the angles, and by gradual improvement of his graphical results renders them consistent with an ellipse, and finally obtains a satisfactory apparent orbit. The elements are then deduced by formulae not very different from those employed by Savary. The method is illustrated by applications to \( \gamma Virginis, a Geminorum, \sigma Coronae Borealis, \xi Ursae Majoris, and 70 Ophinchi (Memoirs, Royal Astronomical Society, Vol. V)

While the process of interpolation invented by Herschel has been extensively employed, and in some cases is very useful, I am satisfied that in general it is better to plot the observations directly and to make a trial ellipse the interpolating curve. This enables us to use both angles and distances and secures all the advantage of judgement which Herschel considered so essential. It often happens that the length of the radius vector changes with extreme rapidity, and as the areas are constant this will imply very great and unequal changes in the angular motion; when the angular velocity of the radius vector is so variable in different parts of the apparent ellipse the course of the interpolating curve becomes altogether uncertain. Under these conditions it is much

better to use the observations directly. It is also recognized that modern measures of distance should be allowed an equal or nearly equal weight in the determination of orbits

After Savary, Encke and Herschel had given such an impetus to the study of sidereal systems, the work was carried forward by Madler and Villarceau, both of whom published a number of orbits with some improvements in the processes of computation.

KLINKERFUES took up the subject about 1856, and in the course of work on several orbits developed very elegant formulae and more practical methods than any which had been used before. His analytical method is marked by rigor and generality, but in the present state of double-star Astronomy is not so practicable as the graphical method treated in section 10

THIELE, some years later, devised an elegant graphical method which has many good points, and is much admired by those who are inclined to determine all the elements geometrically. It will be found in the Astronomische Nachrichten, Band LII\*

Among the more recent investigations those of Professor Kowalsky are remarkable for their extreme elegance and great generality. This method, depending on the general equation of a conic, is all that can be desired from a mathematical point of view, and as simplified by Glasenapp has been extensively used by several computers. The original exposition of the method will be found in the *Proceedings of the Imperial University of Kasan* for 1873, the valuable modification introduced by Glasenapp is given in the *Monthly Notices*, Vol XLIX, p. 278

Other recent investigations which are worthy of special notice include those of Seeliger (Inaugural Dissertation of Schore, Munich, 1889), and of Zwiers (Astronomische Nachrichten, No. 3336)

It is singular that nearly all the methods given above have been developed from the point of view of analysis rather than of practical Astronomy. Burn-ham has recently rendered double-star Astronomy a conspicuous service by reviving the method of representing observations first employed by William Struve (Mensurae Micrometricae, last plate). This consists in plotting the points as determined by the micrometer, and in finding from the places thus laid down the apparent ellipse which best satisfies the observations. We have used a modification of this method throughout the present work, and have discussed it in connection with the graphical method of Klinkerfues, which supplies the process for deriving the elements from the apparent orbit.

<sup>\*</sup>It is also explained by Professor Hall in The Astronomical Journal, No 324

#### § 9. Kowalsky's Method.

We shall now give an exposition of the elegant method of Kowalsky, which seems likely to be the one that will ultimately be adopted by astronomers. The general equation of the ellipse with the origin at any point, here taken at the principal star, is

$$F = ax^{2} + 2hxy + by^{2} + 2gx + 2fy + c = 0,$$
 (1)

which may be reduced to the form .

$$Ax^2 + 2Hry + By^2 + 2Gx + 2Fy + 1 = 0 (2)$$

This equation contains five unknown constants, and hence five values of x and y will enable us to determine the constants of the ellipse. Each observation gives one equation by means of the relations

$$a_0 = \rho_0 \cos \theta_0$$
 ,  $y_0 = \rho_0 \sin \theta_0$  ,

where the x-axis is directed to the north-point. And hence five observations at different epochs will give a determination of the apparent orbit. In practice it is found that a larger number of observations is desirable, and if the observations are sufficiently good, the best results will generally be obtained by a least-square adjustment of the residuals.

When the apparent ellipse is determined, the problem arises to express the elements of the real orbit in terms of the constants which fix the apparent orbit

It is evident that projection does not alter the diameter coinciding with the line of nodes, and this enables us to pass from the apparent to the real orbit. The real orbit is evidently the curve determined by the intersection of the orbit-plane with the elliptical cylinder whose right section is the apparent orbit. In the apparent orbit the axis of x is directed to the north-point, but in passing to the real orbit we shall direct the new axis of x to the ascending node, while the new axis of y will be taken in the plane of the real orbit, and the origin retained at the principal star. Calling the new system of coordinates x', y', z', it is evident that we shall have

$$\begin{array}{lll}
\iota &= \iota' \cos \Omega - y' \sin \Omega \cos \iota + z' \sin \Omega \sin \iota \\
y &= \iota' \sin \Omega + y' \cos \Omega \cos \iota - z' \cos \Omega \sin \iota \\
z &= + y' \sin \iota + z' \cos \iota
\end{array}$$
(3)

If we put z'=0, we shall have the coordinates of a point in the plane of the real orbit. Thus our expressions are simplified, and become equations for turning the axis of x through the angle x, and that of y through the angle x. If we put

$$u = u' \cos \Omega - y' \sin \Omega \cos u \quad , \quad y = u' \sin \Omega + y' \cos \Omega \cos u ,$$

in (2), we shall obtain the equation of the intersection of the plane x'y' with the elliptical cylinder, which is the equation of the real ellipse. Thus we have, on omitting the accents,

$$A (\tau \cos \Omega - y \sin \Omega \cos \iota)^{2} + 2H(\tau \cos \Omega - y \sin \Omega \cos \iota) (\tau \sin \Omega + y \cos \Omega \cos \iota) + B (\tau \sin \Omega + y \cos \Omega \cos \iota)^{2} + 2G (\tau \cos \Omega - y \sin \Omega \cos \iota) + 2F(\iota \sin \Omega + y \cos \Omega \cos \iota) + 1 = 0$$
(4)

The equation of the real ellipse referred to its centre is

$$\frac{a^2}{a^2} + \frac{y^2}{h^2} = 1 \tag{5}$$

If we shift the origin to the focus, we must increase x by ae, and the equation becomes

$$\frac{(\iota + ae)^2}{a^2} + \frac{y^2}{h^2} - 1 = 0, \tag{6}$$

when referred to the principal star.

Now suppose  $\lambda$  to be the angle from the node to the periastron, measured in the plane of the real orbit, then if we turn the axis of x back to the line of nodes, the new coordinates are

$$x\cos\lambda + y\sin\lambda$$
,  $-x\sin\lambda + y\cos\lambda$ 

By means of these values of x and y, equation (6) becomes

$$\frac{(\imath \cos \lambda + y \sin \lambda + ae)^2}{a^2} + \frac{(-\imath \sin \lambda + y \cos \lambda)^2}{b^2} - 1 = 0, \tag{7}$$

the origin is taken at the focus and the axis of x is directed to the node

Now this equation is necessarily identical with (4), which also represents the true ellipse referred to the same axes. Hence, when multiplied by a constant factor  $\epsilon$  the coefficients of the variables must equal the corresponding ones in the equation deduced from the apparent orbit, so that (7) and (4) give

$$\epsilon \left( \frac{\cos^2 \lambda}{a^2} + \frac{\sin^2 \lambda}{b^2} \right) = A \cos^2 \Omega + B \sin^2 \Omega + H \sin 2 \Omega$$
 (8)

$$\epsilon \left( \frac{\sin^2 \lambda}{\sigma^2} + \frac{\cos^2 \lambda}{b^2} \right) = (A \sin^2 \Omega + B \cos^2 \Omega - H \sin 2 \Omega) \cos^2 \iota \tag{9}$$

$$\epsilon \left( \frac{1}{a^2} - \frac{1}{b^2} \right) \sin 2\lambda = (-A \sin 2\Omega + B \sin 2\Omega + 2H \cos 2\Omega) \cos \iota \tag{10}$$

$$\epsilon \frac{e \cos \lambda}{a} = G \cos \Omega + F \sin \Omega \tag{11}$$

$$\epsilon \frac{e \sin \lambda}{a} = (-G \sin \Omega + F \cos \Omega) \cos i \tag{12}$$

$$\epsilon \left( e^2 - 1 \right) = +1 \tag{13}$$

This last equation gives

$$\epsilon = -\frac{1}{1-e^2}$$
 and  $\frac{\epsilon e}{a} = -\frac{e}{a}$ 

Also, since

$$\frac{\epsilon^2 e^2}{a^2} = \frac{e^2}{\mu^2} = \epsilon \left( -\frac{1}{1-e^2} \right) \frac{e^2}{a^2} = \epsilon \left( \frac{1}{1-e^2} \right) \frac{b^2 - a^2}{a^4} = \epsilon \frac{b^2 - a^2}{b^2 a^2} = \epsilon \left( \frac{1}{a^2} - \frac{1}{b^2} \right),$$

we have

$$\frac{e^2}{p^2} = \epsilon \left( \frac{1}{a^2} - \frac{1}{b^2} \right)$$

Now (11) and (12) give

$$e \sin \lambda = -p (F \cos \Omega - G \sin \Omega) \cos \iota$$
;  $e \cos \lambda = -p (F \sin \Omega + G \cos \Omega)$ 

Multiplying (11) by (12) and reducing, we find

$$\frac{e^2}{\mu^2}\sin 2\lambda = (F^2\sin 2\Omega - G^2\sin 2\Omega + 2FG\cos 2\Omega)\cos i$$

From (10) we have

$$\frac{e^2}{p^2}\sin 2\lambda = (-A\sin 2\Omega + B\sin 2\Omega + 2H\cos 2\Omega)\cos i,$$

and hence

$$(F^{2}-G'+A-B)\sin 2\Omega + 2(FG-H)\cos 2\Omega = 0$$
 (14)

If we subtract (9) from (8), we get

$$\frac{e^2}{\mu^2}\cos 2\lambda = \epsilon \left(\frac{\cos^2 \lambda - \sin^2 \lambda}{a^2} - \frac{\cos^2 \lambda - \sin^2 \lambda}{b^2}\right),\,$$

and the difference of the squares of  $e\cos\lambda$  and  $e\sin\lambda$  gives another value of  $\frac{e^2}{p^2}\cos2\lambda$  Equating these two values of  $\frac{e^2}{p^2}\cos2\lambda$ , and solving for  $\cos^2\imath$ , we find

$$\cos^{2} \iota = \frac{(F^{2} - B) \sin^{2} \Omega + (G^{2} - A) \cos^{2} \Omega + (FG - II) \sin^{2} \Omega}{(F^{2} - B) \cos^{2} \Omega + (G^{2} - A) \sin^{2} \Omega - (FG - H) \sin^{2} \Omega}$$
(15)

The forms of the numerator and denominator show that if we put  $\cos^2 \iota = \frac{P}{Q}$ , and hence  $\tan^2 \iota = \frac{Q-P}{P} = \frac{Q+P}{P} - 2$ , we shall get

$$\tan^2 \iota = \frac{F^2 + G^2 - (A+B)}{P} - 2$$

The first member of (9) gives

$$\epsilon \left( \frac{\sin^2 \lambda}{a^2} + \frac{\cos^2 \lambda}{b^2} \right) = \frac{e^2}{\nu^2} \sin^2 \lambda - \frac{1}{\nu^2},$$

and therefore we obtain

$$\frac{e^2}{\nu^2}\sin^2\lambda - \frac{1}{\nu^2} = (A\sin^2\Omega + B\cos^2\Omega - H\sin 2\Omega)\cos^2\nu$$

By squaring (12) we find

$$\frac{e^2}{p^2}\sin^2\lambda \ = \ (F^2\cos^2\Omega + G^2\sin^2\Omega - FG\,\sin2\Omega)\,\cos^2\iota$$

Therefore we have

$$\frac{1}{n^2} = [(F^2 - B)\cos^2\Omega + (G^2 - A)\sin^2\Omega - (FG - H)\sin^2\Omega]\cos^2\iota$$
 (16)

Comparing this with (15), we find  $\frac{1}{p^2} = P$ , and hence

$$\frac{2}{\nu^2} + \frac{\tan^2 \imath}{\nu^2} = F^2 + G^2 - (A+B) \tag{17}$$

Now since

$$\frac{1}{p^2} = P = (F^2 - B) \sin^2 \Omega + (G^2 - A) \cos^2 \Omega + (FG - H) \sin 2\Omega,$$

we easily find

$$\frac{2}{p^2} = F^2 + G^2 - (A+B) - (F^2 - B)\cos 2\Omega + (G^2 - A)\cos 2\Omega + 2(FG - H)\sin 2\Omega$$
 (18)

Hence (17) gives

$$\frac{\tan^2 i}{p^2} = (F^2 - G^2 + A - B)\cos 2\Omega - 2(FG - H)\sin 2\Omega$$
 (19)

If we multiply this equation by  $\sin 2\Omega$ , and (14) by  $\cos 2\Omega$ , and subtract the last result from the first, we get

$$\frac{\tan^2 \iota}{p^2} \sin 2\Omega = -2 (FG - H)$$

If we use  $\cos 2\Omega$  and  $\sin 2\Omega$ , and add the products, we have

$$\frac{\tan^2 \iota}{p^2}\cos 2\Omega = F^2 - G^2 + A - B$$

Therefore we finally obtain the following set of equations:

$$\frac{\tan^{2} \iota}{p^{2}} \sin 2\Omega = -2 (FG - H),$$

$$\frac{\tan^{2} \iota}{p^{2}} \cos 2\Omega = F^{2} - G^{2} + A - B,$$

$$\frac{2}{p^{2}} + \frac{\tan^{2} \iota}{p^{2}} = F^{2} + G^{2} - (A + B),$$

$$e \sin \lambda = -p (F \cos \Omega - G \sin \Omega) \cos \iota,$$

$$e \cos \lambda = -p (F \sin \Omega + G \cos \Omega),$$

$$a = \frac{p}{1 - e^{2}}$$
(20)

These formulae enable us to find  $\Omega, \iota, p, \lambda, r, a$ ; we may then find v at any epoch by the formula

$$\tan (v + \lambda) = \frac{\tan (\theta - \Omega)}{\cos t}$$
, and  $E$  by  $\tan \frac{1}{2}E = \sqrt{\frac{1-e}{1+e}} \tan \frac{1}{2}e$ 

We find M by Kepler's equation

$$M = E - e'' \sin E.$$

And since  $M_2 - M_1 = n (t_2 - t_1)$ , we see that

$$n = \frac{M_2 - M_1}{t_2 - t_1},$$

and

$$P = \frac{360^{\circ} (t_2 - t_1)}{M_2 - M_1} \quad , \quad T = \frac{nt - M}{n}$$
 (21)

PROFESSOR GLASENAPP has proposed a simple method for cases in which good drawings of the apparent orbits have been made, but it is not desired to adjust the results by the method of Least Squares, owing to the uncertainty of the data furnished by observation. In the present state of double-star Astronomy this method is very practicable, and can be advantageously employed in the determination of orbits

In the equation (2)

$$Ax^2 + 2Hxy + By^2 + 2Gx + 2Fy + 1 = 0,$$

we put y = 0, and then find the roots of

$$Ax^2 + 2Gx + 1 = 0 (22)$$

This may be written

$$x^2 + \frac{2G}{A}x + \frac{1}{A} = 0$$
, or  $(x-x_1)(x-x_2) = x^2 - (x_1+x_2)x + x_1x_2 = 0$ ,

where  $x_1$  and  $x_2$  are the roots of the equation, or the abscissae of the points of the orbit on the x-axis.

Hence, by the theory of equations, we have

$$A = \frac{1}{\alpha_1 \alpha_2}$$

Also

$$\frac{2\,G}{A} \; = \; -\left( x_{1} + x_{2} \right) \; , \quad \text{or} \quad G \; = \; - \; \frac{A \left( x_{1} + x_{2} \right)}{2} \; = \; - \; \frac{\left( x_{1} + x_{2} \right)}{2 x_{1} x_{2}} \; . \label{eq:Gaussian_Gaussian_Gaussian}$$

In like manner, putting x = 0, we find

$$By^2 + 2Fy + 1 = 0$$
, or  $B = \frac{1}{y_1y_2}$ ,  $F = -\frac{y_1 + y_2}{2y_1y_2}$ 

Hence when the coordinates of the intersections of the orbit with the axes of x and y are known directly from the apparent orbit, we have the four constants A, B, F, G

And the other constant is given by

$$H = -\frac{Ax^2 + By^2 + 2Gx + 2Fy + 1}{2iy}$$

In finding H we must take a point (x, y) such that the product x y has a large value. It may be desirable to take the mean of several values of H

When all the constants A, B, F, G, H, have been derived, we find the elements by equations (20) and (21)

#### § 10 Graphical Method of Klinkerfues

Suppose  $\alpha$  and  $\beta$  to denote the lengths of the real major and minor semi-axes when projected on the plane tangent to the celestial sphere, and  $\Lambda$  and B to be then position-angles. Then we readily find

$$\alpha^{2} \cos^{2}(A-\Omega) + \alpha^{2} \sin^{2}(A-\Omega) \sec^{2} \iota = \alpha^{2}$$

$$\beta^{2} \cos^{2}(B-\Omega) + \beta^{2} \sin^{2}(B-\Omega) \sec^{2} \iota = b^{2}$$

$$(1)$$

But it is evident that the sum of these equations is the square of the chord between the vertices of the major and minor axes, and the square of the same chord is given by

$$\{\alpha\cos(A-\Omega)-\beta\cos(B-\Omega)\}^2+\{\alpha\sin(A-\Omega)-\beta\sin(B-\Omega)\}^2\sec^2\iota=a^2+b^2$$

Therefore we have

$$\cos(A-\Omega)\cos(B-\Omega) + \sin(A-\Omega)\sin(B-\Omega)\sec^2\iota = 0, \tag{2}$$

and hence

$$\cos^2 i = \tan (A - \Omega) \tan (\Omega - B)$$
 (3)

This equation determines the inclination when the node is known, as the angles A and B are taken directly from the apparent orbit

If we divide the second of equations (1) by the first, we get

$$\frac{b^2\alpha^2}{\alpha^2\beta^2} = \frac{\cos^2\left(B-\Omega\right) + \sin^2\left(B-\Omega\right)\,\sec^2\iota}{\cos^2\left(A-\Omega\right) + \sin^2\left(A-\Omega\right)\,\sec^2\iota}\,,$$

and on substituting for sec21 its value, we find

$$\frac{b^2 \alpha^2}{a^2 \beta^2} = -\frac{\sin 2 (B - \Omega)}{\sin 2 (A - \Omega)} \tag{4}$$

In this equation  $\alpha$  and  $\beta$  are given directly by the apparent orbit, and as e is known, we have also the ratio  $\frac{b^2}{a^2} = 1 - e^2$  Therefore the only unknown quantity is  $2\Omega$ , which we may determine in the following manner. Since the left member of (4) is the square of a real quantity, the right member must be essentially positive, and we may put

$$\tan \zeta = \frac{b\alpha}{a\beta} = \sqrt{\frac{\sin 2 (B - \Omega)}{\sin 2 (A - \Omega)}},$$
 (5)

and since

$$\sec 2\zeta = \frac{\sin 2 (A-\Omega) + \sin 2 (B-\Omega)}{\sin 2 (A-\Omega) - \sin 2 (B-\Omega)} = \tan (A+B-2\Omega) \cot (A-B),$$

we get

$$\tan(A+B-2\Omega) = \sec 2\zeta \tan(A-B) \tag{6}$$

The angle  $\zeta$  is known from its tangent, and hence we easily find  $\Omega$ 

In (3) it is to be observed that  $\cos^2 i$  is necessarily positive and smaller than unity, and hence we have to choose between two values of  $\Omega$  differing by 180°. As it is thus impossible to distinguish between the ascending and descending node, we may arbitrarily take the ascending node between 0° and 180°, and find i by means of (3)

$$\cos^2 \iota = \tan (A - \Omega) \tan (\Omega - B)$$

The angular distance from the node to the periastron is denoted by  $\pi - \Omega = \lambda$ , and is given by the equation

$$\tan (A - \Omega) = \cos i \tan \lambda,$$

or by using (3) we obtain\*

$$\tan^2 \lambda = \frac{\tan(A - \Omega)}{\tan(\Omega - B)} \tag{7}$$

If u denote the argument of the latitude, we have

$$u = v + \lambda = v + \pi - \Omega$$
, and  $\tan u = \sec i \tan (\theta - \Omega)$ ,

where  $\theta$  is the observed position-angle at the given epoch. The latitude l is given by  $\sin l = \sin i \sin u$ 

From the apparent radius vector  $\rho$ , we may find the corresponding true radius vector by  $r_{ij} = \rho_{ij} \sec l_{ij}$ 

The major semi-axis is then found by the polar equation

$$a = \frac{i \left(1 + e \cos v\right)}{1 - e^2} \tag{8}$$

If we take the apastron as the point in question, l will be given by

$$\sin l = \sin i \sin \lambda$$
,

and since  $\rho$  is taken directly from the diagram of the apparent orbit, we easily find  $\tau$ . Then, since  $v=180^{\circ}$ , we have

$$a = \frac{\rho \sec l}{1 + e} \tag{9}$$

To find the time of revolution we take two observations which are widely separated in time, and find the intervening change in the mean anomaly, of we may find from the diagram the part of the area swept over during this interval compared to the whole area of the apparent ellipse If  $\theta_1$  and  $\theta_2$  be the two angles of position, and  $u_1$  and  $u_2$  the corresponding arguments of the latitude, we shall have

$$\tan u_1 = \sec i \tan (\theta_1 - \Omega) ,$$
  
$$\tan u_2 = \sec i \tan (\theta_2 - \Omega) ,$$

and then

$$v_1 = u_1 - \lambda \qquad , \qquad v_2 = u_2 - \lambda \; ,$$

whence the mean anomalies are easily found. Instead of computing the change of the mean anomaly, it is generally preferable to measure up the area swept

<sup>\*</sup> $A-\Omega$  and  $\lambda$  must be in the same of in opposite quadrants. Throughout this work  $\lambda$  is taken in the direction of the motion

over by the radius vector during the interval, and determine the period by the law of areas

Suppose that  $t_1$  and  $t_2$  be the dates of two widely-separated observations, then the double area swept over by the radius vector will be

$$\int_{t_1}^{t_2} \rho^2 \, \frac{d\theta}{dt}$$

Putting a', b' for the major and minor semi-axes of the apparent ellipse, it is evident that the time of revolution will be given by

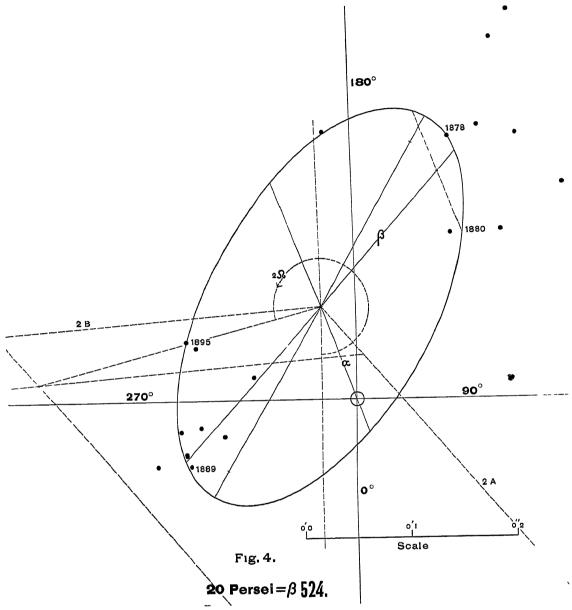

$$P = \frac{2\pi a'b'(t_2 - t_1)}{\int_{t_1}^{t_2} \frac{d\theta}{dt}}$$
(10)

In case the period is computed from the change in the mean anomalies, we have

$$n = \frac{M_2 - M_1}{t_2 - t_1} \quad , \quad P = \frac{360^{\circ}}{n} \tag{11}$$

The periastion passage is given by  $T = t_1 - \frac{M_1}{n}$ , or it may be found from the principle of areas, in the same manner as the period. Thus, since the double areal velocity is known, we simply determine the double area included between a given radius vector and the periastion, and ascertain the intervening time. This interval is to be added to or subtracted from the time of observation, according as the date chosen is before or after the epoch of periastron passage.

To find the node by graphical construction we draw from the centre of the ellipse lines whose position-angles are 2A and 2B; then, parallels to these at distances related as  $a^2\beta^2$  to  $b^2a^2$ . Connect the intersection of the parallel lines with the centre, and this will give a line whose position-angle is  $2\Omega$ . This construction is easily deduced from (4), and in practice will be found extremely exact. The graphical method is highly practicable, and in the present state of double-star Astronomy is the one which should generally be preferred. The possible maccuracies of the method are greatly inferior to the uncertainty still attaching to the best orbits. The principal difficulty experienced by computers consists in the finding of a satisfactory apparent orbit.

The apparent orbit of 20 Perser =  $\beta$ 524 is shown above. We find by the figure r = 0.7.38,

To obtain the apparent orbit it is best to make use of both angles and distances. If the precession has a sensible effect upon the position angles, it is desirable to refer the observations to a common epoch by applying the formula

$$\Delta\theta = n \sin\alpha \sec\delta (t - t_0) \tag{12}$$

where n = 20''.04987, and  $t_0$  is the date of observation, t the epoch adopted. We then combine the individual measures of the best observers into suitable annual means, and plot the resulting positions on a convenient scale. The approximate normal places thus defined are subject to two conditions.

- (1) That the areas swept over by the radius vector shall be proportional to the times,
- (2) That the apparent ellipse which satisfies the law of areas shall conform also to the observed distances.

The ellipse which satisfies these conditions must be found by trial. Fine planimeter measurement renders the approximation comparatively rapid, and when a satisfactory ellipse has been obtained we derive the elements and compare the computed with the observed places

We first determine e, then compute the ratio  $\frac{b^2\alpha^2}{a^2\beta^2}$ , and find the node by graphical construction, it is then easy to find i,  $\lambda$ , P, T, and a, as explained in the foregoing method. If further refinement of the elements be desired, recourse must be had to differential formulae.

It is to be remarked, however, that the assumption of constant areal velocity is equivalent to postulating the absence of unseen bodies or other disturbing influences, and as this is not yet fully established, the orbits which best represent the angular motion are not necessarily correct, as may be seen in the case of 70 Ophiuchi If it is necessary to violate the distances in a conspicuous manner in order to preserve the law of the areas, the result must be looked upon with suspicion In the present state of double-star Astronomy most of our orbits must be regarded as tentative, but when they shall finally be improved there is no doubt that, if the motion is really undisturbed, both angles and distances will be well represented.

If it is desired to compute  $\rho$  and  $\theta$  from the elements, we may employ the formulae

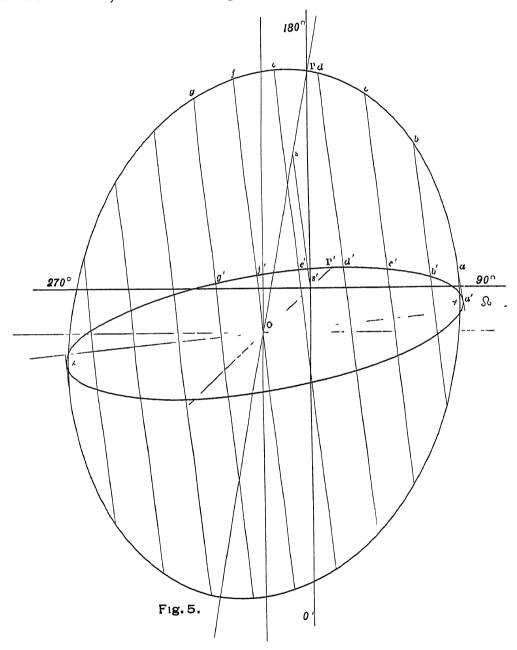

$$\tan \left(\theta - \Omega\right) \; = \; \tan \left(\lambda + v\right) \, \cos \imath \qquad , \qquad \rho \; = \; a \, \left(1 - e \, \cos E\right) \, \frac{\cos \left(\lambda + v\right)}{\cos \left(\theta - \Omega\right)} \, .$$

The element  $\lambda$  is counted from the node between 0° and 180°, in the direction of the motion, in case of retrograde motion the formula for  $\theta$  becomes

$$\tan (\Omega - \theta) = \tan (\lambda + v) \cos \iota$$

## Graphical Method of Finding the Apparent Orbit of a Double Star

It is frequently desirable to project the apparent orbit of a double star from the elements, this interesting and useful result may be effected in a

very simple manner. In order to make the process more intelligible we shall apply it to a particular case, and for this purpose we select the orbit of 9  $Argûs = \beta 101$ 

The elements required for this purpose are the following.

Eccentricity,  $e=0.700\pm0.02$  Major semi-axis,  $\alpha=0''.6549$  Node,  $\Omega=95^{\circ}.5$  Inclination,  $\iota=77^{\circ}.72$  Node to perastron,  $\lambda=75^{\circ}.28$ 

We lay down on suitable drawing paper two lines which intersect each other at right angles, and thus mark the four quadrants of position-angle. The intersection of these lines will be the centre of the real orbit and also the centre of the apparent orbit. The line of nodes is then drawn through the centre, having a position-angle of 95° 5. In like manner we lay down the line whose position-angle is  $\Omega + \lambda = 170^{\circ}$  78, and this will be the major axis of the real ellipse.

We now adopt a convenient scale, which will give a length on the drawing paper of 10 or 12 inches for the major axis

With close stars 0"1 may represent one or two inches of the scale, so that the work can be done with the highest degree of accuracy. From the centre the length of the major semi-axis (0".6549) is laid down on the line just drawn, and the distance of the foci of the ellipse from the centre will be ae (0".6549 × 0.70) The ellipse is then drawn in the usual manner.

We now lay off points on the line of nodes at equal distances from the centre of the ellipse, and through these points draw lines aa', bb', cc', dd' etc, perpendicular to the line of nodes. The lengths of these lines on either side are found in seconds of arc by the scale used, and then multiplied by the cosine of the inclination ( $\cos 77^{\circ} 72 = 0.214$ ), the resulting values are marked on the corresponding lines at a', b', c', d', e', f', etc, on both sides of the line of nodes.

The points thus determined will lie on the arc of the true ellipse as seen from the Earth, and when we pass the curve through them, we have the apparent orbit of the double star.

To find the position of the star in the apparent ellipse, we multiply the distance of the focus of the real ellipse from the line of nodes by the cosine of the inclination, and thus find the point s', which will be the position of the central star in the projected orbit. A line Os'P', drawn from the centre through this point to intersect the arc of the apparent ellipse, gives the position-angle of the real major axis, and the position of the real periastron

Having thus obtained the position of the central star in the apparent orbit, it only remains to draw through the principal star lines parallel to those inter-

secting at the centre and marking the four quadrants, which may now be crased In the figure the lines which mark the four quadrants are somewhat heavier than the rest, so that they are easily recognized.

Thus a very simple process of projection enables us to trace the outline of the apparent orbit of any star when the required elements are given, and from the observed positions it is possible to see at a glance whether the apparent orbit represents the observations satisfactorily. It only remains to add that in the case of retrograde motion, the angle  $\lambda$  (which should always be counted in the direction of motion, while the ascending node should be taken between 0° and 180°) must for purposes of graphical representation be taken as negative, and the position-angle of the major axis of the real ellipse becomes  $\Omega = \lambda$ , whereas for direct motion the angle is  $\Omega + \lambda$ , as in the case of  $\Omega = \Lambda$ 

### § 11. Formulae for the Improvement of Elements

The foregoing graphical method, when judiciously applied, will give elements having all the accuracy which can be desired in the present state of double-star Astronomy. But as some improvement of a very refined character will ultimately be possible, we shall present the differential formulae which may be employed to effect these slight variations of the elements.

The formulae for finding the position-angle heta from the elements are

$$M = n (t - T) = E - e'' \sin E,$$

$$\tan \frac{1}{2} v = \sqrt{\frac{1 + e}{1 - e}} \tan \frac{1}{2} E,$$

$$\tan (v + \lambda) \cos \iota = \tan (\theta - \Omega)$$

Since  $\theta$  is a function of the six elements,  $\Omega$ , i,  $\lambda$ , e, T, n, we have

$$d\theta \; = \; \frac{\partial F(\theta)}{\partial \Omega} \; d\Omega \; + \frac{\partial F(\theta)}{\partial \lambda} \; d\iota + \frac{\partial F(\theta)}{\partial \lambda} \; d\lambda \; + \frac{\partial F(\theta)}{\partial \rho} d\varrho \; + \frac{\partial F(\theta)}{\partial T} \; dT \; + \frac{\partial F(\theta)}{\partial n} \; dn$$

When the variations of the elements are finite, but small, we have the approximate formula,

$$\theta_{\circ} - \theta_{\circ} = \Delta\theta = A\Delta\Omega + B\Delta i + C\Delta\lambda + D\Delta e + G\Delta T + II\Delta n$$
,

where A, B, C, D, G and H, denote the partial differential coefficients From the equations which enable us to compute  $\theta$  we obtain these coefficients by partial differentiation with respect to the several elements. Thus we find

$$A = +1,$$

$$B = -\cos^{2}(\theta - \Omega) \tan(v + \lambda) \sin \iota,$$

$$C = \sec^{2}(v + \lambda) \cos^{2}(\theta - \Omega) \cos \iota,$$

$$D = \left(\frac{2 \tan \frac{1}{2} E}{(1 - e) \sqrt{1 - e^{2}}} + \sqrt{\frac{1 + e}{1 - e}} \frac{\sec^{2} \frac{1}{2} E \sin E}{1 - e \cos E}\right) \cos^{2} \frac{1}{2} v C,$$

$$G = -\sqrt{\frac{1 + e}{1 - e}} \frac{\sec^{2} \frac{1}{2} E \cos^{2} \frac{1}{2} v C}{1 - e \cos E},$$

$$H = \frac{(t - T)}{v} G$$

The formulae usually employed by astronomers for effecting the differential corrections of the elements thus take the form

$$A_1\varDelta\Omega+B_1\varDelta\iota+C_1\varDelta\lambda+D_1\varDelta e+G_1\varDelta T+II_1\varDelta n-\varDelta\theta_1=0$$
 ,  $A_2\varDelta\Omega+B_2\varDelta\iota+C_2\varDelta\lambda+D_2\varDelta e+G_2\varDelta T+II_2\varDelta n-\varDelta\theta_2=0$  ,

$$A_{\nu}\Delta\Omega + B_{\nu}\Delta\iota + C_{\nu}\Delta\lambda + D_{\nu}\Delta e + G_{\nu}\Delta T + H_{\nu}\Delta n - 1\theta_{\nu} = 0$$

There are six quantities to be deduced from this system of equations, a solution by the method of Least Squares will generally ensure the best results. In the above form of the equations it is tacitly assumed that the residuals in angle represent absolute displacements of the companion in space, regardless of its distance from the central star, which is evidently inexact. The importance of a given error in angle increases in proportion to the length of the radius vector, and as the distance of the companion is generally very unequal in different parts of the apparent orbit, the formulae should be so modified as to render the absolute displacements of the observed positions a minimum. This improvement can be effected as follows. We shall assume that the major axis can be best determined from the apparent orbit, which serves as an interpolating curve analogous to that recommended by Sir John Herschell, and hence this element need not be regarded as variable. It is, therefore, required to compute the slight variations for the other six elements.

Let us suppose that the value of  $\rho$  corresponding to the position-angle  $\theta_o$  is  $\rho_a$ , this value may be computed or measured graphically from the diagram. Let the corrected angle and distance be  $\theta_o$  and  $\rho_o$  respectively. Then it is easy to see that the displacement of a point on the apparent orbit due to the correction of the elements will be given by

$$\Delta s = \sqrt{\left(\frac{\rho_a + \rho_c}{2}\right)^2 (\theta_o - \theta_o)^2 + (\rho_a - \rho_o)^2}$$

In case the length of the radius vector in the apparent orbit is practically constant, the last term of the radical becomes insensible, and the displacement in space at a given distance is proportional to the displacement in angle But as many of the orbits are very eccentric and highly inclined, and the radius vector therefore changes rapidly, the best result can be obtained only by the use of the complete residuals expressed above. In computing these values numerically we may express  $(\rho_a - \rho_c)$  in degrees by the formula  $2\binom{\rho_a-\rho_c}{\rho_s+\rho_c}$  57°3, and since  $(\theta_o-\theta_c)$  is already given in degrees, we must express the coefficient as an abstract number in units of the major semi-axis, in order to give the displacements in angle weight proportional to the length of the radius vector

Since the second term of the resulting expression under the radical sign

$$I\theta^{\circ} = \sqrt{\left[\binom{\rho_{o} + \rho_{o}}{2u}(\theta_{o} - \theta_{o})^{\circ}\right]^{2} + \left[\frac{2(\rho_{o} - \rho_{c})}{(\rho_{o} + \rho_{o})} \quad 57^{\circ} 3\right]^{2}}$$

will often be very small, it will frequently be sufficient to use the first term only, or in other words, to assign the residuals in angle weights proportional to the lengths of the radii vectores

This method of improving the elements will be found very much shorter than that involved in the process of correcting both angles and distances by separate differential formulae, and will lead to the same results without loss of accuracy

# § 12. A General Method for Facilitating the Solution of Kepler's Equation by Mechanical Means\*

The standard works on planetary motion, such as Gauss' Theoria Motus, Oppolzer's Bahnbestimmung, and Watson's Theoretical Astronomy, give methods for solving Kepler's Equation which are very satisfactory when the eccentricity of the orbit is small, and also when this element is large, as in the case of most of the periodic comets. When the eccentricity is small, an expansion in series, usually by Lagrange's Theorem, enables us to find the eccentric anomaly with the desired facility. The series frequently employed has the form

$$E_0 = M + e'' \operatorname{sm} M + e'' \binom{e}{2} \operatorname{sm} 2M +$$

<sup>\*</sup>Monthly Notices, June, 1805, also Note in Monthly Notices for December, 1805

To the approximate value  $E_0$ , obtained from a few terms of this series, we apply a correction resulting from the expansion by Taylor's Theorem.

$$E = E_0 + \frac{dE_0}{dM_0} dM_0 +$$

The equation of Kepler gives

$$\frac{dM_0}{dE_0} = 1 - e \cos E_0,$$

and since

$$dM_0 = M - M_0,$$

we find two terms of the series to be

$$E = E_0 + \frac{M - M_0}{1 - e \cos E_0}$$

Successive applications of this formula will readily yield the true value of the eccentric anomaly. But when the eccentricity is considerable the expansion in series fails to converge with the desired rapidity. On the other hand, when the orbits differ but little from parabolas, the solution can readily be found by means of special tables, such as those given by Gauss, Watson and Oppolizer.

It is very remarkable that among the many solutions of Kepler's Equation discovered by mathematicians there is not one, so far as I am aware, which has come into general use among astronomers that is applicable to ellipses of all possible eccentricities.

The method to which I desire to direct attention is a modification of the graphical method originally invented by J. J. Waterston (Monthly Notices, 1849–50, p 169), and subsequently rediscovered by Dubois (Astronomische Nachrichten, no 1404) The method was afterwards discussed by Klinkerfues in his Theoretische Astronomie, p 17, but so far as I am aware\* it never came into practical use until employed in the investigations embodied in this work

Suppose we construct, on a convenient scale, a semi-circumference of the curve of sines,  $y = \sin x$  In practice it is desirable to use millimetre paper, and a convenient scale is obtained by taking one degree of the arc as five millimetres, so that the scale may easily be read to 0°.1 The origin of the arc is taken at the origin of coordinates, and as the scale along the axis of abscissae extends from 0° to 180°, it will have a length of 90 centimetres.

In the figure let OM represent the mean anomaly, and suppose from M

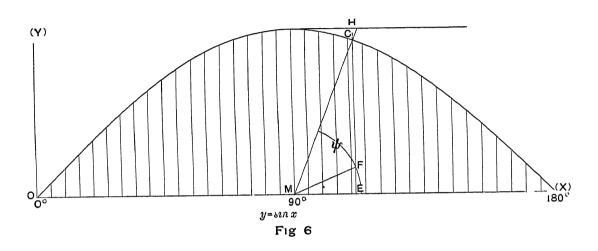

<sup>\*</sup>Monthly Notices, December, 1895

we draw a right line making an angle  $\Psi$  with the axis of abscissae, the angle  $\Psi$  being defined by the equation

$$\tan \Psi = \frac{1}{e}$$

Let the abscissa of the point C, determined by the intersection of the right line MC with the sine curve, be denoted by E. Then we evidently have

$$OE - ME = OM$$

Thus, denoting the arc OE by E, and observing that  $e \sin \Psi = \cos \Psi$ , we find that  $e \sin \Psi = ME$ , the radius in the case of  $\sin \Psi$  being such that  $\sin \Psi$  is always equal to  $\sin E$ 

Hence we get

$$OE - ME = OM$$
,

or

$$E - e \sin E = M,$$

which is the Equation of Kepler.

Therefore we conclude that if for an orbit of given eccentricity we construct a triangle CME (in practice this may be made of cardboard) and apply the vertex M of the triangle to the successive mean anomalies, the base coinciding with the x-axis, the intersection of the hypothenuse with the curve of sines will give at once abscissae which are the corresponding eccentric anomalies. Any actual diagram such as we have described will be subject to slight inaccuracies of construction, owing to the transcendental nature of the sines, and hence we cannot obtain solutions of absolute precision. But it is entirely possible to get approximate solutions exact to 0°1, and this work can be done with the greatest rapidity. It is merely necessary to slide the base of the

triangle along the x-axis, placing the vertex M at the points corresponding to the different values of the mean anomaly, and reading off the corresponding eccentric anomalies.

This triangle device is rendered possible by virtue of the fact that  $\psi$  is constant in  $\tan \Psi = \frac{1}{e}$ , and we may observe that in case of elliptic orbits the angle F can vary only from 45° in the case of a parabola to 90° in the case of a This method is therefore directly applicable to ellipses of every possible eccentricity, and the accuracy of the solution is always substantially the same In the case of parabolic motion, however, the method fails, since when  $\Psi = 45^{\circ}$ the hypothenuse MC is tangent to the sine curve at the origin the hypothenuse MC intersects the curve  $y = \sin x$ , and the intersection will be well defined except when e approaches unity and M is very small. In such cases it is best to use the Special Tables or the Theory of Parabolic Motion Solutions exact to 0°1 are often sufficient in the present state of double-star observation, and we readily see how great is the practical value of this method in comparing a long series of observations with a given set of elements. One hundred approximate solutions of Kepler's Equation, accurate to 0° 1, may be obtained by this method in less than half an hour; while if e lies between 035 and 0.85 probably a skilled computer could not obtain the same results by the ordinary method in less than a day. Thus the time and labor required for this work is much diminished, and it is clear that the chances of large error are correspondingly reduced.

If a curve of sines were engraved on a metallic plate it would be an easy matter to devise a movable protractor which could be set at any angle, such a piece of apparatus would serve for every possible elliptic orbit, and would Considering the immense labor devolving upon last for an indefinite time astronomers in the computation of the motion of the heavenly bodies, it would seem that such a labor-saving device might be advantageously employed in the offices of the astronomical ephemerides However, as several astronomers have prepared tables for facilitating the solution of Kepler's Equation in the case of orbits which are not very eccentric, such an apparatus would be useful chiefly in work on the more eccentric asteroids, the double stars, and the periodic In dealing with the motions of these bodies the labor saved would be very considerable, and we might hope that the apparatus here suggested would come into actual use But in case this instrument of precision could not be successfully manufactured, owing to its limited commercial use, it is easy for a working astronomer to construct a curve of sines on millimetre paper

This can be mounted on a suitable wooden board, and a triangle of cardboard will give the solutions of Kepler's Equation for any given orbit

Thus, while the graphical method, originally proposed by Waterston, afterwards independently discovered by Dubois, and subsequently discussed by Klinkerfues, was suggested many years ago, it does not appear that it has vet come into general use, and therefore it deserves the careful attention of It is worthy of remark that a method of such great practical astronomers importance should rest in comparative oblivion during half a century, at a time when astronomers were constantly working on the motions of periodic comets and double stars, but it is probable that neither Waterston nor Dubois recognized the great generality and high value of the method in practical work Since writing the paper which I communicated to the Royal Astronomical Society in June, 1895, I have had occasion to make great use of the method in revising the orbits of double stars, and have found it not only the easiest and most rapid process yet invented, but one altogether so satisfactory that we may predict its universal adoption by astronomers The simplicity and generality of the method and the rapidity and accuracy with which solutions can be obtained, invite the inference that in the nature of the case the method is probably ultimate, and is not likely to be improved upon in any future age

While this method is of special importance in dealing with the motions of double stars, owing to the wide range of their eccentricities, it will evidently be almost, if not quite, equally important in the case of periodic comets and the asteroids. But in dealing with comets and planets, where we desire very exact solutions of Kepler's Equation, it will be necessary to correct the approximate values by the formula

$$\Delta E_0 = \frac{M - M_0}{1 - e \cos E_0},$$

where  $M_0$ ,  $E_0$  are the approximate values of the mean and eccentric anomalies A second correction will ensure all the accuracy desirable in planetary and cometary ephemerides \*

<sup>\*</sup>Among the other means for solving Kepler's Equation we mention especially the tables of  $\Lambda$  signal (Englemann, Leipzig), Doberck, A N, Bd 189, and a graphical method by Mr II C Plummer, Monthly Notices, March, 1896

## CHAPTER II.

ON THE ORBITS OF FORTY BINARY STARS.

### Introductory Remarks

The present chapter is occupied with detailed researches on the motions of the forty stars whose orbits can be best determined at this epoch. The material presented for each star has been collected from all available sources and is very complete. It is highly improbable that any important records have been overlooked, and since we have drawn the material almost wholly from original sources, future investigators will have little need to repeat the labor involved in collecting observations of these stars prior to 1895.

In some cases we have not used all of the available measures, either because the observations appeared to be defective, or because good observations were obtained too late to be incorporated in the discussions, which were not changed unless the elements adopted were found to be inconsistent with the new material. In the main, our choice of observations has been guided by the assumption that it is possible to find an orbit which is consistent with undisturbed elliptical motion. The observations have justified a violation of this principle only in the case of 70 Ophiuchi, which presented anomalies too large to be attributed to errors of observation. If the course of time should show that other stars also are perturbed, it will become apparent that we have not always made the best choice of the material now available.

In the determination of these orbits a number of distinguished astronomers have contributed their observations in advance of publication. They have not only sent manuscript copies of valuable measures, but have offered their work with a generosity which merits my most grateful acknowledgement. Among those to whom we return thanks are: M. G. BIGOURDAN, National Observatory, Paris, Profs. G. C. Comstock and A. S. Flint, Washburn Observatory, Madison; Prof. S. De Glasenapp, Director of the Observatory, Imperial University, St. Petersburg; Prof. G. W. Hough, Director of the Dearborn Observatory, Evanston, Ill; Prof. V. Knorre, Royal Observatory, Berlin; T. Lewis, Esq., Royal Observatory, Greenwich, M. W. Maw, Esq., Private

Observatory, London, Prof G. V Schiaparelli, Director of the Royal Observatory, Milan, Prof W Schur, Director of the Royal Observatory, Gottingen, John Tebbutt, Esq., Private Observatory, Windsor, N S Wales, Dr. H. C Wilson, Goodsell Observatory, Northfield, Minn

I have also had the constant cooperation of Professors Burnham and Barnard, who have made valuable suggestions in addition to contributing important observations, some of which were secured expressly for this work. In the investigation of the individual orbits my friends Mr. Geo K Lawton, Mr. Eric Doolittle, and Mr. F. R. Moulton have at different times rendered valuable assistance in the execution of a large part of the computations. Without such assistance, uniformly characterized by both zeal and enthusiasm, it would have been impossible to have completed the determination of so many orbits in so short a time. To these gentlemen I acknowledge my deep and lasting obligations. Besides aiding me in the preparation of Chapter I, Mr. Moulton has assisted in arranging the manuscript for the printer, and in reading the proofs, and thus not only expedited the work but also ensured greater accuracy than otherwise would have been possible

While no effort has been spared to ensure exactness in the computations and in the drawings, it can scarcely be hoped that in dealing with so great a mass of material all errors have been avoided. There is reason, however, to believe that such errors as may exist in the work will have no appreciable effect upon the final results

A number of the orbits embodied in this Chapter have been published in the Astronomical Journal, the Astronomische Nachrichten, and the Monthly Notices of the Royal Astronomical Society, references to these sources will be found in the appropriate places

When Herschel discovered this pair he measured the angle and repeated his observation the following year, without finding any sensible change.\* Beginning with 1823, Struve followed the star for ten years; and from the measures thus secured he discovered that the system is a binary in rapid orbital motion. Since Struve's time the star has been carefully measured by many of the best observers, so that there is abundant material upon which to base an orbit which seems likely to be substantially correct.

Having collected all the published observations of \$\Sigma 3062\$ from original sources, I have formed for each year a mean position which is the arithmetical mean of the mean results obtained severally by the best observers. In accordance with the experience of Struve, Otto Struve, Dembowski, and Burniam these yearly means may be held to furnish the most trustworthy basis for the elements of an orbit. The following is a table of the orbits hitherto published for this star.

P	T	e	а	ß	ı	λ	$oldsymbol{\Lambda}$ uthority	Source	
146 83	1834 01	0.57536	0.9982		38 6	42 2	Müdler, 1847	Doip Obs IX, 180 Die Fixst-Syst

	1834 88 1835 508		$egin{array}{c} 127 \ 1270 \end{array}$	$\begin{array}{c} 38.6 \\ 39.15 \end{array}$			Doberck, 1877 Doberck, 1879		

By the method of KLINKERFUES we find the following elements.

	•
P = 10461 years	$\Omega = 47^{\circ} 15$
T = 183626	$i = 43^{\circ} 85$
e = 0.450	$\lambda = 90^{\circ} 90$
a = 1'' 3712	$n = +3^{\circ} 441355$

<sup>\*</sup> Astronomische Nachrichten, 3292

70 Σ 3062

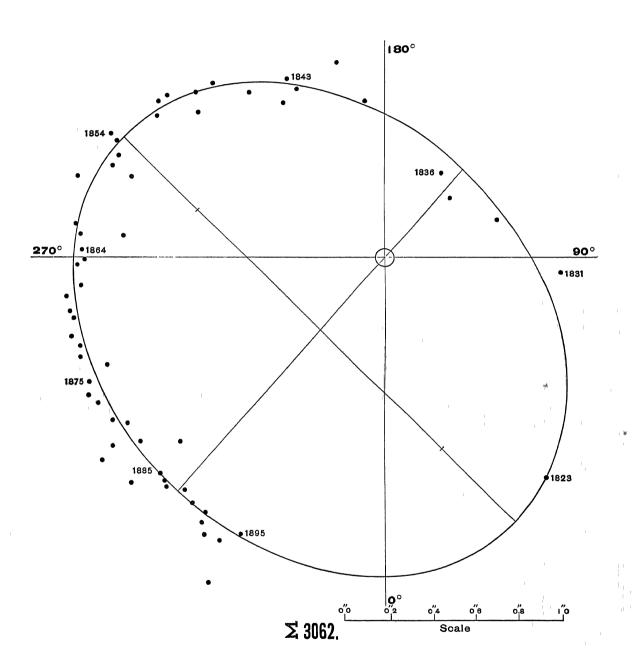

#### Apparent orbit.

Length of major axis = 2'' 526Length of minor axis = 1'' 984Angle of major axis  $= 45^{\circ} 7$ Angle of periastron  $= 138^{\circ} 4$ Distance of star from centre = 0'' 446

It will be seen that these elements are very similar to those derived by von Fuss in 1867. The following comparison of the computed and observed places shows that the above elements are highly satisfactory, and that the true elements of this remarkable binary will hardly differ sensibly from the values here obtained.

COMPARISON OF COMPUTED WITH OBSERVED PLACES

It will be seen that there are occasional systematic errors both in the angles and in the distances, and in some cases these deviations appear to be rather more extensive than we should expect in the work of the best observers; but the star has some peculiar difficulties, especially as regards the distance, and on the whole the measures are fairly accordant for so close an object

This star deserves the careful attention of observers, as the next 20 years will give the material which will make the orbit exact to a very high degree. It may be pointed out that the system has a considerable proper motion in space, in  $\alpha + 0^{\prime\prime} 346$ , in  $\delta + 0^{\prime\prime} .020$ , and therefore the chances are that it has a sensible parallax. If the parallax could be determined it would give us the absolute dimensions of the system and the combined mass of the components — two elements of the highest interest in the study of the stellar systems.

## $\eta$ CASSIOPEAE = $\Sigma$ 60.

 $\alpha = 0^{h}~42^{m}~0$  ,  $\delta = +57^{\circ}~18'$  4, yellow , 7, purple

Discovered by Sir William Herschel, August 17, 1779

At the date of discovery SIR WILLIAM HERSCHEL found the distance\* of the component to be 11".09, and estimated the angle at 70° At the epoch 1780 52 he found the distance 11"46, but made no measure of the angle of position until 1782 45, when it proved to be 62°07 HERSCHEL observed the angle to be 70°8, in 1803, but made no measure of the distance The earliest observation of both angle and distance is a rough measure by Bessel, in 1814; and although his angle is nearly correct, it is evident from the subsequent work of Struve that the distance is much too small. Since the time of Struve  $\eta$  Cassiopeae has been followed by nearly all of the best observers, so that we have good material upon which to base an investigation of the orbit.

Although the observations of  $\eta$  Cassiopeae do not suffice to fix all the elements so well as might be desired, yet it appears that the range of uncertainty is comparatively unimportant, except in the case of the periodic time, which may possibly differ several years from the value here derived. Some of the orbits found for  $\eta$  Cassiopeae by previous computers are indicated in the following Table of Elements.

N,

We find the following elements for this celebrated binary

```
P = 195 \ 76 \ \text{years} Q = 46^{\circ} \ 1

T = 1907 \ 84 i = 45^{\circ} \ 95

e = 05142 \lambda = 217^{\circ} \ 87

a = 8'' \ 2128 n = +1^{\circ} \ 83899
```

#### Apparent orbit

Length of major axis	_	15" 80
Length of minor axis	=	10" 24
Angle of major axis	=	55° 8
Angle of penastron	=	254° 5
Distance of star from centie	=	3" 80

The table of computed and observed places shows that these elements are highly satisfactory. But the rapid orbital motion near periastron will make it possible to effect a slight improvement in about ten years

The parallax of the system recently determined by DR HERMANN S DAVIS of Columbia College seems to be entitled to great weight; and yet the value is so large that with these elements the mass is only 0 166 that of the sun. The distance of the system is 464540 times the distance of the earth from the sun, and the semi-major axis of the orbit is 1854 astronomical units. This mass is very small for the size of the system, and if the parallax of 0".43 be confirmed, say, by Heliometer measures, our ideas of the nature of the stellar systems will have to be considerably modified. The parallax of 0".154 found by Otto Struve in 1856, from measures with the micrometer, gives a distance for the system of 1339400 astronomical units. The semi major axis comes out 53 33 times the distance of the earth from the sun, and the combined mass proves to be 3 96

The companion is at present near the line of nodes, and its relative motion in the line of sight is near its maximum value. The brightness and width of this pair is such as to justify an application of the spectroscopic method for determining parallax developed in § 5, Chapter I

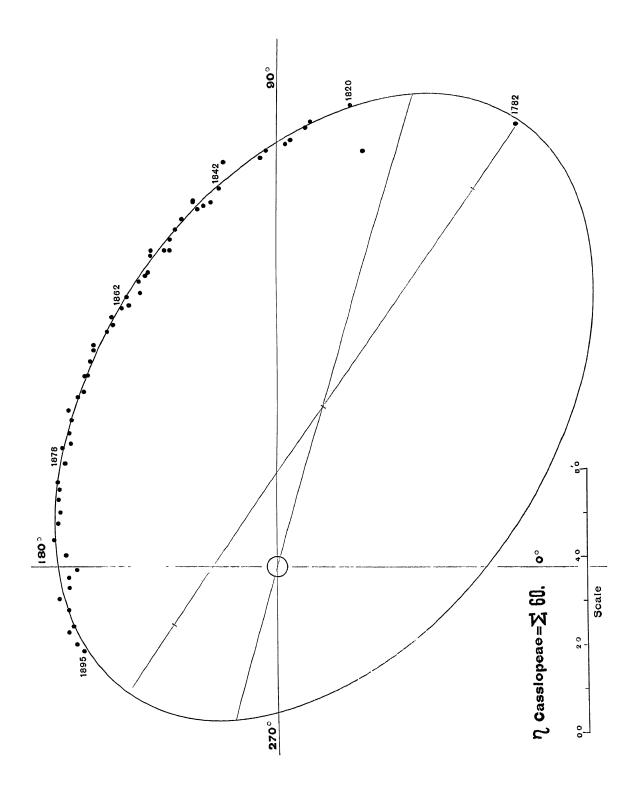

In this connection we may point out the great importance of the determination of the parallaxes of double rather than of single stars. The parallaxes of single stars are of comparatively little interest, since they give us only the distance and hence the velocity perpendicular to the line of vision, and the radiation compared to that of the sun. On the other hand, the parallaxes of double stars whose orbits are known give us, besides these data, the absolute dimensions of the orbits and the combined masses of the components—two elements of the highest importance in the study of the systems of the universe  $\eta$  Cassiopeae is remarkable for the great angular distance of the components,

and for the rapid proper motion of the system. Both of these circumstances support the belief that the star is comparatively near to us in space, and render it certain that the parallax is sensible

In 1881 Mr. Ludwig Struve discussed the relative motion of the components about the common center of gravity of the system, and from his investigation it follows that  $\frac{M_3}{M_1} = 0.268$ , or the masses of the two stars, according to Otto Struve's parallax, are respectively 2.90 and 1.06 times the combined mass of the sun and earth. The companion is therefore more massive than the sun and moves in an ellipse nearly twice the size of the orbit of Neptune, but the eccentricity is so large that in periastron the companion would come considerably within the orbit of the outer planet, while at apastron it would recede to more than three times that distance

Since Otto Struve's discovery of this extraordinary binary in 1842 the companion has described nearly an entire revolution, but as the orbit is very eccentric and highly inclined nearly all the observations lie in the narrow region included between position-angle 120° and 100° Only in recent years has it been possible for observers to prove the reality of orbital motion, some ten years ago the object was found to be getting more and more difficult, and

hence it became clear that the distance was diminishing. In 1886 Newcomb found the distance 0"29 and the angle 101°; in small telescopes the star When Burnham examined the object in 1889 he found it appeared single exceedingly difficult even with the 36-inch refractor of the Lick Observatory, and during 1890 the companion was wholly invisible When the star was examined in 1891 it was found that the companion had changed to the opposite quadrant, the angle being 312°6 and the distance so excessively small that it was estimated at 0"05±. Barnard's examination of the object in 1893 gave the key The companion had swept rapidly round to 121°8, thus passto the situation. ing over about 320° of position angle since the measure in 1889 at once undertook an investigation of the orbit, and obtained a very satisfactory His paper, in the Monthly Notices for December, 1893, contains set of elements an illustration of the apparent orbit, and a complete list of measures down to We have added the measures made since that date, and derived a set of elements very similar to that found by BURNHAM His elements are:

```
P = 54 \text{ 8 years} \Omega = 113^{\circ} 5

T = 1892 \text{ 1} i = 78^{\circ} 9

e = 0 875 \lambda = 200^{\circ} 8

a = 0'' 37
```

We find the following elements of  $\gamma$  Andromedae:

```
P \stackrel{.}{=} 540 \text{ years} Q = 113^{\circ} 4

T = 1892 1 i = 77^{\circ} 85

e = 0 857 \lambda = 200^{\circ} 1

a = 0'' 3705 n = -6^{\circ} 6667
```

Apparent orbit:

```
Length of major axis = 0'' 706

Length of minor axis = 0'' 084

Angle of major axis = 109^{\circ} 9

Angle of penastron = 289^{\circ} 0

Distance of star from centre = 0'' 298
```

The table of computed and observed places shows a good agreement for an object of this difficulty. The residuals are easily within the limits of the errors of observation. The orbit is remarkable for its great eccentricity and high inclination. Both of these elements are well defined, and the values given above will never be materially altered. Thus the error in the eccentricity can hardly surpass  $\pm 0.02$ , while a variation of one year in the period is to be regarded as improbable. In regard to the shape of the real orbit,  $\gamma$  Andromedae takes its place between  $\gamma$  Virginis and  $\gamma$  Centauri. These three remarkable systems are also similar as regards the relative brightness of their components,

which in each case are nearly equal. Since the companion of  $\gamma$  Andromedae is now within the reach of ordinary telescopes the accompanying ephemeris will be useful to astronomers

The discovery of the companion of Sirius is one of the justly celebrated events of modern Astronomy. It extended to the regions of the fixed stars the principle of theoretical prediction which has proved so admirable in the solar system, and which in the hands of Leverrier and Adams had led to the discovery of Neptune. Bessel had occasion to make a careful examination of the proper motions of a considerable number of stars, including Sirius and Procyon. The two dog stars, instead of moving uniformly on the arcs of

great circles, seemed to trace out irregular sinuous paths across the sky, and a further study of these anomalies convinced Bessel that the two stars were perturbed by invisible bodies. In 1844 he wrote, in a letter to Humboldt "I adhere to the conviction that *Procyon* and *Surius* form real binary systems, consisting of a visible and an invisible star. There is no reason to suppose luminosity an essential quality of cosmical bodies. The visibility of countless stars is no argument against the invisibility of countless others."

In 1857 the suggestion of Bessel was taken up by Peters, who made an investigation of the observed inequalities, and found the following elements for the orbit described by *Surius* about the common centre of gravity of the system:

Periastron passage = 1791 431 Mean yearly motion = 7° 1865 Period = 50 01 years Eccentricity = 0 7994

In 1861 the question was again examined by Safford, who transmitted to Brunnow an investigation which assigned to the companion a position-angle of 83°.8 for the epoch 1862 1. A short time afterwards, on Jan. 31, 1862, Mr Alvan G. Clark was trying the new 18-inch object glass of the Dearborn telescope, and on pointing the instrument on Sirius exclaimed: "Why, father it has a companion!" And sure enough the faint but massive disturbing body announced by Bessel was seen within a few degrees of the place assigned by the theoretical astronomers. It now became a matter of great interest to ascertain from the motion of the new companion whether it was really the disturbing body, a few years showed that it had sensibly the required motion, and left no doubt of the identity of the two objects. In 1864 Auwers undertook a new determination of the elements based on all the observations, and found:

 Peniastron passage
 = 1793 890

 Mean annual motion
 = 7° 28475

 Period
 = 49 418 years

 Eccentricity
 = 0 6010

A definitive determination afterwards published gave the following results:

P = 49 399 years  $\Omega = 61^{\circ} 96$  T = 1843 275  $\iota = 47^{\circ} 14$  e = 0 6148  $\lambda = 18^{\circ} 91$ a = 2'' 331

When the micrometrical measures began to accumulate, various computers made new investigations of the orbit. The following table of elements is very

The last set credited to DR AUWERS were based on all the obseromplete ations up to 1892

During 1890 the distance of the companion became so small that it was ost in the rays of the large star, even when viewed with the 36-inch refractor of the Lick Observatory As it was evident that no further observations could be made until the object emerged on the other side, BURNHAM collected all the neasures with great care and embodied them in his important paper in the Monthly Notices for April, 1891

The orbit which we have given in this work is very similar to that found by Burnham, except that the eccentricity is higher and more nearly in accord with the value of this element found by Auwers The orbit is based wholly on the micrometrical measures, and the data used in deriving the mean places nave been very carefully selected

We find the following elements of the orbit of Sirius

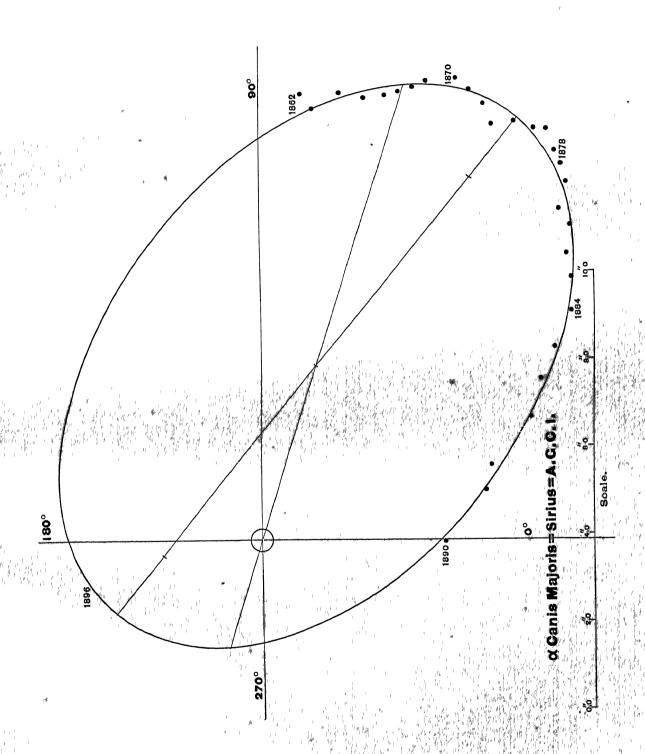

P = 5220 years  $\Omega = 34^{\circ}3$ T = 189350 $i = 46^{\circ}77$ e = 0.620 $\lambda = 131^{\circ}03$  $a = 8'' \, 0316$  $n = -6^{\circ} 89655$ 

## Apparent orbit

Length of major axis = 14'' 63Length of minor axis = 9'' 50Angle of major axis  $= 50^{\circ} 7$ Angle of periastron  $= 252^{\circ} 4$ Distance of star from centre = 4" 16

The comparison of the computed with the observed places shows an extremely satisfactory agreement, and we are led to believe that the elements given above will prove to be near the truth. The differences between these elements and those found by Auwers are not greater than might be expected from the material used in the two cases Adopting the foregoing elements and GILL's parallax of 0" 38, we find the mass of the system to be 3.473 times that of the sun and earth; the major semi-axis comes out 21.136 astronomical units. Thus the system of Sirrus is a magnificent one, having 3 47 times the mass of the planetary system, and slightly larger dimensions than the orbit of The masses, according to Auwers, are in the ratio 1:2.119; the planet *Uranus* or, in units of the sun's mass, 1.113 and 2.360 respectively. The future observation of this star is a matter of the highest interest. There is some reason to suppose that Sirius is very much expanded, more nearly resembling a nebula than the sun; if this inference be true, the action of the companion will raise enormous bodily tides in the mass of Sirius Since the height of the tides varies inversely as the cube of the distance, it will follow that the tidal elevation at periastron will be about 80 times higher than at apastron. There would thus arise a periodic disturbance in the mass of Sirius depending on the revolution of the companion. It seems probable that high tides would increase the radiation of Sirius, and hence if it were possible to make photometric measures of absolute accuracy, or of such a character that the brightness could be compared at intervals of 25 years, it might some day be possible to detect the alteration in brightness arising from the tidal action of the companion.

The excessive faintness of this massive body is an extraordinary anomaly which is not easily explained. From the shape of the orbit, however, we may believe that the system has been formed by the usual process, and for some reason the companion has rapidly become obscure. As the companion is apparently still self-luminous, its darkness is not so conspicuous as the excessive brilliancy of *Sirius*. The change in the color of *Sirius* since ancient times is even more remarkable.

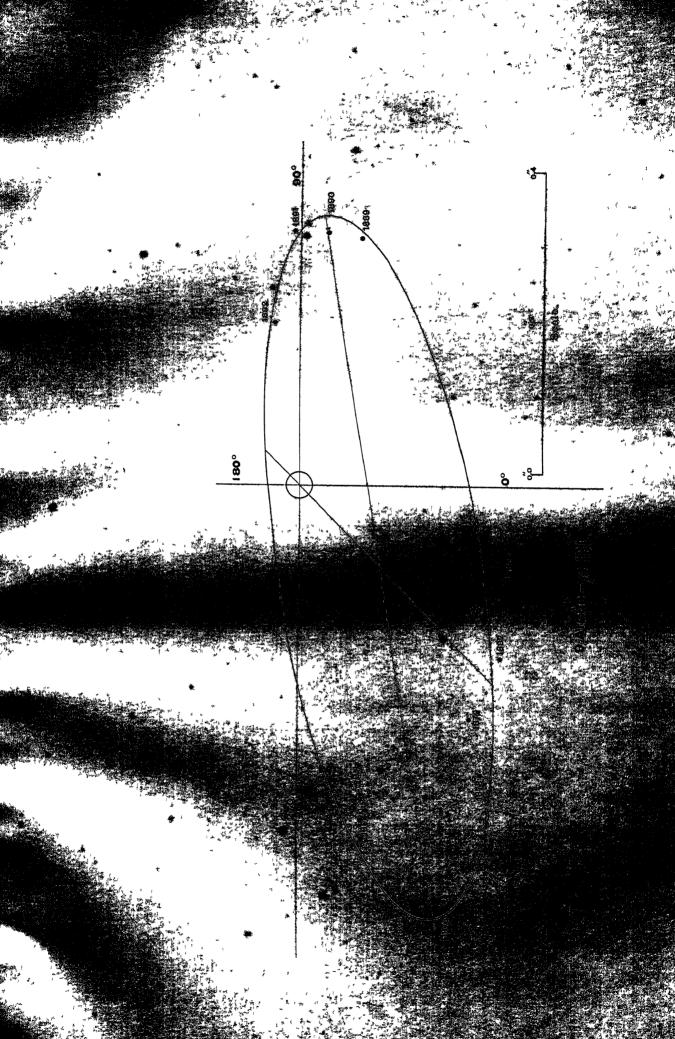

## $9 \text{ ARGUS} = \beta 101.$

Discovered by Burnham with his celebrated six-inch Clark Refractor, March 11, 1873

The first investigation of the orbit was made by Glasenapp and published in the *Monthly Notices* for June, 1892. His elements are

$$P = 40 54 \text{ years}$$
  $\Omega = 116^{\circ} 7$   
 $T = 1844 02$   $i = 59^{\circ} 2$   
 $e = 0 090$   $\lambda = 251^{\circ}.3$   
 $a = 0'' 45$   $n = +8^{\circ} 880$ 

Burnham revised this orbit, in May, 1893, and by relying on the distances as well as the angles, arrived at an apparent ellipse of very different character, from which we derived the following elements (Astronomy and Astrophysics, June, 1893)

```
P = 23\,377 \text{ years} \Omega = 95^{\circ}\,75

T = 1892\,706 i = 76^{\circ}\,87

e = 0\,68 \lambda = 73^{\circ}\,92

a = 0''\,612 n = +15^{\circ}\,3998
```

It did not take long to decide which set of elements was to be preferred.\* BARNARD examined the star with the 36-inch refractor of the Lick Observatory in December, 1893, and found that since 1892.05 the radius vector of the companion had swept over about 180°, so that the small star was in the fourth quadrant I took occasion recently, while measuring double stars with the 26-inch refractor of the Leander McCormick Observatory of the University of Virginia, to measure 9 Argûs on three good nights. The observations confirm those of Barnard, and show that Burnham's apparent orbit is not far from the truth. With the new measures, it seemed worth while to re-investigate the orbit; accordingly, from a consideration of all the observations, I find the following elements of 9 Argûs

```
P = 22\,00 \text{ years} \Omega = 95^{\circ}5

T = 1892\,30 \iota = 77^{\circ}72

e = 0\,70 \lambda = 75^{\circ}28

\alpha = 0''\,6549 n = +16^{\circ}.3636
```

Apparent orbit:

Length of major axis = 0'' 941Length of minor axis = 0'' 267Angle of major axis  $= 99^{\circ} 2$ Angle of periastron  $= 134^{\circ} 5$ Distance of star from centre = 0'' 152

It is confidently believed that these elements will prove to be nearly correct, in spite of the small number of observations upon which they are based.

<sup>\*</sup>Astronomische Nachrichten, 3297

It will be seen that the residuals are very small for such a close and difficult star, and it is evident that future observations will not change the present orbit materially, although it is desirable to secure additional exact measures which will improve the elements as much as possible. If adequate attention is given to this object, its orbit will soon be one of the best in the heavens. A short ephemeris is

t	$oldsymbol{ heta_o}$	$ ho_{\mathfrak o}$	t	θο	Po
1896 3	285 8	0"59	1899 3	$295^{\circ}2$	0"55
1897 3	288 8	0 60	1900 3	2990	0 51
1898 3	291 9	0 59			

As the eccentricity of the orbit is well determined by the rapid motion of the companion round the periastron, the established conspicuous magnitude of this element must be regarded as the most remarkable phenomenon of the system.

For the next few years the star will be relatively easy, and double-star observers should give it particular attention

The closer components of this ternary (or quarternary) system have been found to revolve rapidly in a period of about sixty years, while the remote component moves much more slowly, and probably will complete its orbit in six or seven centuries Both stars move retrograde, and the system thus made up is one of great interest to the physical astronomer. From the time of WILLIAM STRUVE the observations are both abundant and exact, and hence the orbit of the close pair can now be determined with a high degree of pre-We shall treat only of the close binary, neglecting the remote companion and the dark body which Professor Seeliger supposes to attend it. It is evident that the third component will exercise a considerable disturbing influence upon the close pair, but Professor Seeliger has shown that this influence is probably obscured by the large errors incident to the measurement of a system which is never much wider than one second of arc. Assuming that the motion will be sensibly undisturbed, we shall deduce the orbit of the closer pair by the same process which is employed in the case of other binaries. The motion of this system has been investigated by numerous computers; the following list of orbits is fairly complete:

 				1			4 17	Source

An examination of all the measures led to the mean places given in the accompanying table; from these we find the following elements

$$P = 60 \text{ 0 years}$$
  $\Omega = 88^{\circ} 7$   
 $T = 1870 40$   $i = 7^{\circ} 4$   
 $e = 0 340$   $\lambda = 264^{\circ} 0$   
 $a = 0'' 8579$   $n = -6^{\circ} 000$ 

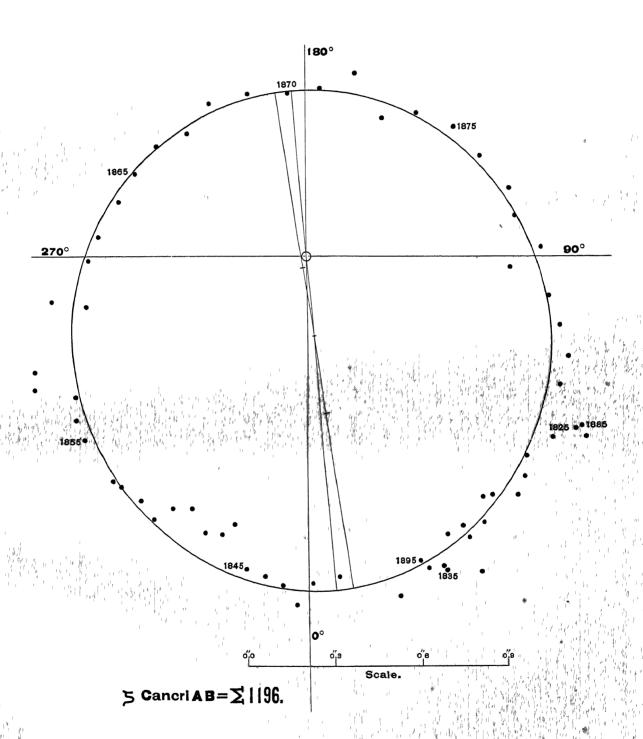

Apparent orbit.

Length of major axis = 1'' 701Length of minor axis = 1'' 632Angle of major axis  $= 8^{\circ} 8$ Angle of periastron  $= 184^{\circ} 9$ Distance of star from centre = 0'' 290

The comparison of the computed with the observed places shows a good agreement, and indicates that no radical change in the above elements is to be expected. The period is perhaps uncertain by half a year, while the eccentricity can hardly be varied by more than  $\pm 0.03$ . The motion extends over more than one revolution, and is well represented by the above elements in all parts of the orbit. The apparent ellipse is remarkable for its circularity, and the small inclination renders the motion almost the same in the apparent as in the real orbit. The general interest thus attaching to this system is greatly enhanced by problems arising from the perturbations of the third star and its theoretical companion.

A more critical investigation of these problems will commend itself to the attention of astronomers; the best results will depend upon the reduction of exact observations by the refined methods of analysis. In the present state of micrometrical measurement, a very refined treatment is seriously embarrassed by the errors of observation, but the methods of physical Astronomy ought eventually to enable us to improve the theory of the motion of the system, which is here taken as undisturbed

The following is a short ephemeris for the use of observers.

$oldsymbol{t}$	$\theta_c$	$ ho_c$	t	$ heta_\iota$	ρι

WILLIAM STRUVE rated the magnitudes of the components of this pair at 7.5 and 78\* respectively. Recent observations with the 26-inch refractor of the Leander McCormick Observatory of the University of Virginia convince the writer that the brightness of the components has been over-estimated by at least a whole magnitude. The star is close and very faint, and the natural difficulty of the object will doubtless account for the rather large discordances in some of the observations.

As  $\Sigma 3121$  has been observed for many years, and the pair revolves with great rapidity, several orbits have been determined by previous investigators. The following is believed to be a complete list of the elements hitherto published:

P	T	е	a	រះ	ı	λ	Authority	Source

Some of the observations are vitiated by sensible systematic errors, so that occasionally our best observers differ by so much as 12°; and in succeeding years the angles are made to retrograde where they ought to be steadily advancing. Under these circumstances the residuals may be considered small, and the elements very satisfactory for so close and difficult a star. In following this star, observers should take every precaution against systematic error, since the orbit is highly inclined, and a small error in angle greatly affects the distance. Good observations are essential for any further improvement of the elements.

		Ерни	EMERIS		
t	$\theta_c$	ρ,	t	$\theta_c$	$\rho_c$
1896 30	13 5	0 64	1899 30	207	0 77
1897 30	162	0 69	1900 30	227	0.79
1898 30	18 5	074			

Since the companion is now approaching its maximum distance, the star will be relatively easy for a number of years

# ω LEONIS = Σ1356.

At the time of discovery Sir William Herschel estimated the position-angle \* to be between 95° and 100°, but later in the year found by measurement that the angle was 110°.9. The pair was soon found to be in slow orbital motion, and in 1804 Herschel concluded that since 1782 the change in angle had amounted to +19° 59′, and that the distance had sensibly increased. When the star was thus recognized as binary, it naturally claimed the attention of the principal double-star observers, and accordingly since the time of Struve, a long list of measures has been secured But while the closeness of the companion in most parts of the apparent ellipse has made the pair a classic test-object for the dividing power of small telescopes, it has, on the other hand, rendered micrometrical measurement extremely difficult, and some of the observations are therefore far from satisfactory. In spite of the fact that the measures

<sup>\*</sup> Astronomische Nachrichten, 3311

are sometimes difficult to reconcile, the angles and distances of the best observers, when properly combined, in conjunction with the important principle of the preservation of areas, enable us to fix the apparent ellipse with a relatively high degree of precision, and the resulting elements are found to be incapable of any large variation. The orbit is based chiefly upon the observations of Herschel, Struve, O Struve, Dawes, Dembowski, Burniam, Hall, Schiaparelli, and the measures which the writer recently secured at the McCormick Observatory in Virginia. The elements of ω Leones are.

The elements given above confirm the substantial accuracy of the orbit found by Hall, and represent the observations as a whole remarkably well. The changes which future observations will introduce are likely to be very small.

The following is an ephemeius for the next five years:

### EPHEMERIS

t	$ heta_c$	$ ho_c$	t	$\theta_c$	$\rho_c$
$1896\ 28$	$108^{\circ}7$	$0^{''}85$	1899 28	$11\overset{\circ}{2}4$	0 90
1897 28	1100	0 87	1900 28	113 5	0.91
1898 28	$111\ 2$	0.88			001

It is to be noted that the distance is steadily increasing, and that for many years the pair will be relatively easy. A number of observers of late years have sensibly underestimated the distance. Owing to the closeness of  $\omega$  Leonis and its slow orbital motion, one would naturally think that this brilliant system probably has a small mass, and is comparatively near us in space, for if the mass be large, the slow motion of so close a system would indicate that it is very remote, and the resulting brightness of the components would be very great. The eccentricity of this orbit is so well determined that the value given above can hardly be in error by so much as 0.01, and a correction of half this amount does not seem probable.

# $\varphi$ URSAE MAJORIS = $\varphi \Sigma 208$ .

Although this close and rapid binary was discovered by Otto Struve, the first observation was secured by Madler, whose measures supplement Struve's work in a very happy manner, and enable us to fix the original position of the companion with much precision. For a long time these two astronomers alone followed the motion of the system, but in later years it has received occasional attention from several other observers. The stars are nearly equal in magnitude, and hence a few of the recorded angles require a correction of 180°. The arc already described amounts to about 270°, and as this covers the most critical parts of the orbit, most of the elements are defined with the desired precision. The chief difficulty encountered by observers lies in the closeness of the components, which places them beyond the reach of small, and even of moderate-sized, telescopes. The pair is, however, gradually widening out, and in a few years will be much more accessible to measurement.

The following elements of this star have been published by previous computers.

	P	$m{T}$	е	a	Ω	r	λ	Authority	Source
1	15 4 91 9	1877 12 1885 4	0 788 0 <b>4</b> 5	0″54 0′29	105 3 165 7		$72\overset{\circ}{1}$ $19\ 0$	Casey, 1882 Glas, 1892	A N 2417 A N 3119

Using all the available measures, we find the following elements

P = 970  years	$\Omega = 160^{\circ}3$
T = 18840	$\iota = 30^{\circ} 5$
e=0440	$\lambda = 15^{\circ} 9$
a = 0'' 3443	$n = +3^{\circ}7114$

### Apparent orbit:

```
Length of major axis = 0'' 69

Length of minor axis = 0'' 5.3

Angle of major axis = 167^{\circ} 6

Angle of periastron = 174^{\circ} 1

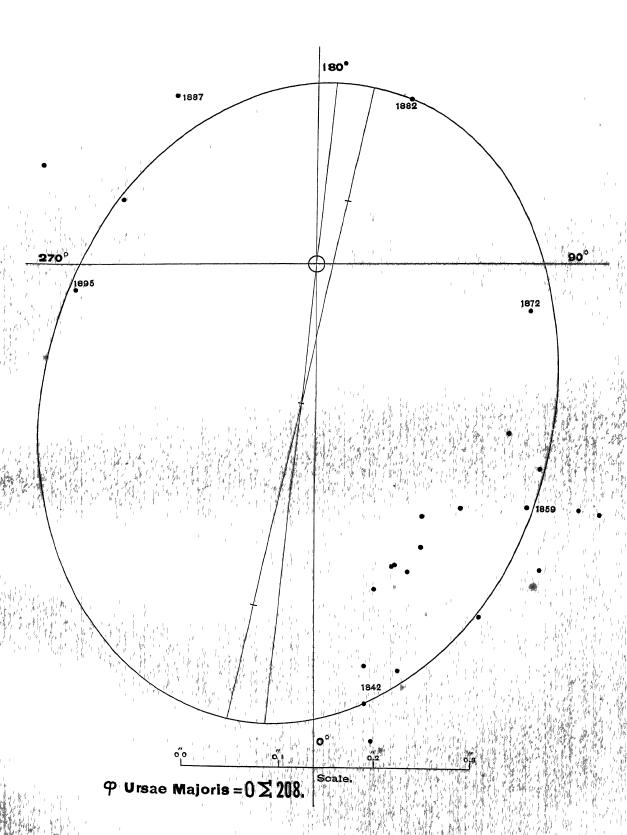

Distance of star from centre = 0'' 149
```

It will be seen that this orbit is essentially similar to that found by GLASENAPP. The table of computed and observed places shows so satisfactory an agreement for this close and difficult object that we may regard these elements as substantially correct, and confidently conclude that such alterations as future observations may render necessary will be of minor importance

Some changes will doubtless be required in all the elements, but the two elements of chief interest, the period and the eccentricity, will hardly be varied

by more than five years, and  $\pm 0.03$  respectively. It is desirable to have the theory of this system carefully confirmed, and observers with good telescopes will find it worthy of regular attention. The motion is still tolerably rapid, but is gradually slowing up, as will be seen in the following ephemeris.

t	$\theta_c$	$\rho_c$	$oldsymbol{t}$	$\theta_c$	ρ <sub>c</sub>

This celebrated system was first measured by Herschel in 1781 A 1cpetution of the measures in 1802 and 1804 showed\* that the smaller star had a rapid relative motion (*Phil. Trans.* 1804, p 363), and indeed gave indications for the first time that the motion of certain double stars is of an orbital nature  $\xi$  Ursae Majoris thus enjoys the unique distinction of having first aroused interest in observational proof of the universality of the Newtonian law. This

<sup>\*</sup>Astronomische Nachrichten, 3323

star also led Savary in 1827 to derive a method for finding the orbit of a double star on gravitational principles, and the first orbit ever computed appeared in the Connaissance des Temps for 1830. When Savary's method for finding double-star orbits had been successfully applied to \(\xi\) Ursae Majoris, the subject was taken up by Encke and Herschel, who published methods of superior elegance and of greater practical utility, with the result that numerous orbits were soon computed.

The rapid orbital motion of  $\xi$  Ursae Majoris insured it ample attention, and accordingly since the time of Sir John Herschel and Struve, measures have been secured annually by the best observers. The number of orbits computed for this star is very large, the following list is fairly complete:

It will be seen that among the more recent orbits there is no wide range of values, and yet the elements are by no means identical. The different results depend upon the observations used and the method of computation employed.

From an investigation of all the observations, I am led to the following elements:

$$P = 60\ 00\ \text{years}$$
  $\Omega = 100^{\circ}\ 8$   
 $T = 1875\ 22$   $\iota = 55^{\circ}\ 92$   
 $e = 0\ 397$   $\lambda = 126^{\circ}\ 33$   
 $\alpha = 2''\ 508$   $n = -6^{\circ}\ 0000$ 

### Apparent orbit:

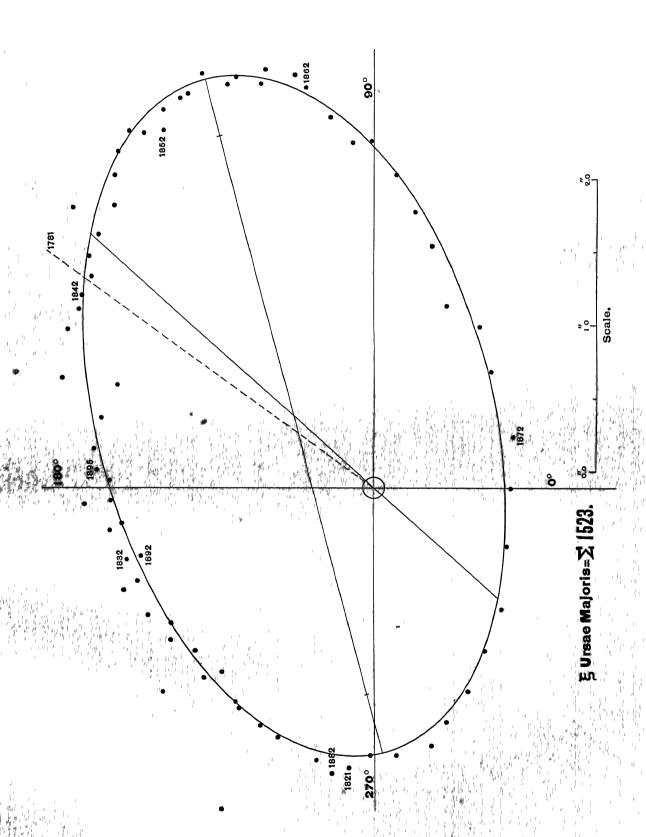

SHA PROPERTY

Length of major axis	=	4″ 76
Length of minor axis	=	2" 70
Angle of major axis	=	104° 6
Angle of penastron	=	$318°\ 0$
Distance of star from centre		0" 75

The following table of computed and observed places shows that these elements are extremely satisfactory

COMPARISON OF COMPUTED WITH OBSERVED PLACES

Future observations are likely to produce only very slight alterations in the above values. Thus the period is not likely to be in error by more than one-tenth of a year, and the error in the eccentricity can hardly surpass  $\pm 0.005$  Indeed the orbit  $\xi$  Ursae Majoris is practically all that can be desired in the present state of double-star measurement. In order to effect any further improvement of the orbit, astronomers will need to take every precaution against systematic errors, and rough measures by inexperienced observers are unlikely to prove to be of any considerable value.

We remark, however, that continued observation of this star is desirable, because the micrometrical measures of skilled observers will be valuable in throwing light upon the question of the existence of dark bodies or other disturbing influences, and in proving with all possible experimental accuracy that the force which retains the companion in its orbit is directed exactly towards the central star

*ξ Ursae Majoris*, like *ζ Herculis*, has a large proper motion in space, and this circumstance in connection with the brilliancy of the components, conduces to the belief that the system is comparatively near the earth. Measurement for parallax has never been attempted, but if suitable comparison stars could be found, effort in this direction would be likely to prove successful

Since the discovery of this pair by Otto Struve, the companion has described an arc of 305°. The object is always close and difficult, and hence the measures are by no means so good as could be desired, yet when account is taken of both angles and distances, there is reason to believe that elements based on the observations now available will never be greatly changed. Mr Gore is the only computer who has previously investigated the orbit of this pair; using the measures prior to 1886, he found the following elements.

P = 6345  years	$\Omega = 124^{\circ}2$
T = 1881  15	$i = 47^{\circ} 35$
e = 03629	$\lambda = 71^{\circ} 97$
a = 0'' 339	•

*05* 234. 113

We find the following orbit of  $O\Sigma 234$ :

P = 770 years  $\Omega = 157^{\circ} 5$  T = 1880 10  $\iota = 50^{\circ} 6$   $\iota = 0 302$   $\iota = 206^{\circ} 6$  $\iota = 0'' 3467$   $\iota = 44^{\circ} 6754$ 

 ${f Apparent~orbit}$ 

Length of major axis = 0'' 695Length of minor axis = 0'' 437Angle of major axis  $= 158^{\circ} 0$ Angle of periastron  $= 355^{\circ} 2$ Distance of star from center = 0'' 098

The accompanying table shows that these elements are very satisfactory; the period is perhaps uncertain by five years, and the eccentricity by perhaps Larger variations in these elements are not to be anticipated probably worth noting that Burnham's distance in 1891 is sensibly smaller than the computed distance, although the angle agrees perfectly. By this we are not to infer that he under-measured the distance with the great Refractor of the Lick Observatory, but that all small distances with a great Telescope appear diminished in comparison with their magnitude in a small instrument—a phenomenon due mainly to the diminution of the spurious discs under the superior separating power of great Telescopes. The computer must therefore take account of the inequality of the distances due to the different power of the Telescopes employed; but as most of the observations of  $O\Sigma 234$  were made with instruments of about 15-inch aperture, I preferred to make the scale of the major axis such, that on the whole the computed would agree with the observed distances

The observation of this star which I made at Madison, is discordant in angle (AJ 359), and hence I am led to think that an error of 30° occurred in reading the circle, the unreduced reading was 94°.3, whereas it doubtless should read 64°3. As the angle was estimated at 130°, this correction is amply justified.

If good observations can be secured for the next decade, this orbit can be rendered very exact. The following ephemeris will be useful to observers:

For a number of years after the discovery of this pair, Otto Struve alone noted the position of the companion, but as his measures soon established the rapid motion of the system, Dembowski, Hall, Schiaparelli, and other subsequent observers have contributed to the material now available for the investigation of the orbit.

The observations are not very numerous, but for an object of this difficulty, they are comparatively good

The arc described by the companion since 1844 is only 166°, and yet the motion around the apastron of the apparent orbit defines the elements with considerable precision Doberok is the only astronomer who has previously investigated the motion of this pair; his elements are as follows:—

P	T	e	<b>*</b> a	ស	ı	λ	Authority	Source
94 4 94 406	1839 1 1839 10	0 500 0 5870	0 <sup>"</sup> 98 1 066	99 <sup>°</sup> 6 96 28	$5\overset{\circ}{4}5$ $60\ 22$		Doberck,1879 Doberck,1879	

A careful study of all the observations leads to the following elements:

$$P = 80 \text{ 0 years}$$
  $\Omega = 81^{\circ} 7$   
 $T = 1834 30$   $\iota = 49^{\circ} 32$   
 $e = 0 324$   $\lambda = 137^{\circ} 78$   
 $\alpha = 0'' 8690$   $n = +4^{\circ} 5$

A comparison of the computed with the observed places shows a very satisfactory agreement, and we cannot doubt that the elements given above will be found to approximate the truth. The period remains uncertain by perhaps five years, and the eccentricity may be varied by  $\pm 0.05$ , but larger alterations in these elements are not to be expected. The motion of this pair will be accelerated in approaching periastron, and hence for a good many years will

In the course of the three years following the discovery, Herschel secured several micrometrical measures with his seven-inch equatorial, but it appears that the records he has left us in his sweeps with the 20-feet reflector are much nearer the truth as regards the position-angle of the stars at that epoch. It is singular that his measures with the equatorial give angles almost identical with that of the pair at the present time (356° 4), while his estimates made under the superior power of the reflector give the angle as 340°  $\pm$ . A careful study of all of his observations of  $\gamma$  Centauri (Results of Observations at the Cape of Good Hope, pp. 211, 256, 269), and of the other measures by subsequent astronomers leaves no doubt that his estimates with the reflector are essentially correct, while for some reason the measures taken with the equatorial are vitated by systematic errors which render them worthless. In the above list of measures I have inserted Herschel 's notes, with a view of throwing light upon this interpretation of his observations.

Contrary to the opinion of Herschel, it is now evident that the motion of  $\gamma$  Centauri is retrograde; and hence we perceive that the radius vector has swept over nearly an entire revolution since 1835. The recent measures of Tebbutt, to whom we are so much indebted for observations of this star, prove beyond doubt that the distance of the components in angle 350° must be at least 1"48; and hence it could easily have been divided by Herschel with his seven-inch equatorial. He says, however, that the object was "extremely close and very difficult, at least as close as  $\gamma$  Virginis;" and since it is known that  $\gamma$  Virginis, to which Herschel gave regular attention, was less than 0".7,

	we i district the state of the
	,

we may conclude that the distance of  $\gamma$  Centauri did not surpass 1"0. If this be the approximate distance at the epoch 1835 25 we see that the angle must have been substantially what Herschel estimated with the reflector, and we are thus enabled to reconcile his measures with those of later observers. His estimate of  $340^{\circ}\pm$  for the angle is based on three nights' work and can hardly be in error by more than two degrees. If we adopt the position thus indicated

and make use of the measures secured since 1856, we shall obtain an orbit which is near the truth, and the resulting elements will never be greatly changed. Mr. Gore is the only computer who has previously investigated the orbit of this binary, using Herschiel's equatorial measures, and relying mainly on the angles, he found:

```
P = 61 88 \text{ years} \Omega = 177^{\circ} 95

T = 1840 84 \iota = 84^{\circ} 1

\iota = 0 6316 \lambda = 46^{\circ} 81

\iota = 1'' 50
```

Making use of the mean places given in the following table, and basing our work on both angles and distances, we are led to the following elements of  $\gamma$  Centauri:

```
P = 880 \text{ years} \Omega = 4°6

T = 18480 \iota = 62°15

\epsilon = 0800 \lambda = 194°3

\alpha = 1"0232 n = -4°0911
```

#### Apparent orbit

```
Length of major axis = 2'' 10

Length of minor axis = 0'' 58

Angle of major axis = 0^{\circ} 1

Angle of perfastron = 177^{\circ} 8

Distance of star from centre = 0'' 794
```

The period here found may be uncertain by perhaps three years, and the eccentricity by  $\pm 0.03$ , but larger variations in these important elements are not to be expected. The orbit of  $\gamma$  Centauri is remarkable for its considerable inclination and high eccentricity, which renders the pair very difficult in the periastron part of the apparent ellipse. Binaries with equal components are very frequent among double stars, and are types of systems which possess a peculiar interest when studied in respect to their evolution.

It is clear that  $\gamma$  Centauri will move rather slowly for a good many years, but it deserves the regular attention of southern observers. The following is a short ephemens

The observations of this celebrated system date back almost to the beginning of double-star Astronomy. The only double star previously recognized which has proved to be binary is a Centauri † It was resolved into its components in December, 1689, by Father Richard, at Pondicherry, India. On putting one eye to the telescope, and looking at the heavens with the other, Bradley found the two components of  $\gamma$  Virginis to be approximately in line with the naked-eye stars a and  $\delta$  Virginis; this allineation gives a positionangle of 330°8 at the epoch 1718 20. Such an observation has of course some historical interest, but is worthy of little consideration in the discussion of a modern double-star orbit. Neither can any confidence be placed in the position for 1720, which was calculated from a lunar occultation observed by Cassini while searching for evidence of an atmosphere surrounding the Moon

The observation which results from the Catalogue of Tobias Mayer would be entitled to more weight were it not for the uncertainty of double-star positions deduced from differences of right ascension and declination.

Therefore in the present discussion of the orbit I have relied principally upon observations since the time of William Struve, but have not entirely ignored the measures of Sir William Herschel, which appear to be as good as could be expected from the means at his disposal After an examination of all the observations, it appeared advisable to base the orbit mainly upon the work of the great standard observers. This sifting of the observational material is rendered the more necessary by virtue of the great number and miscellaneous character of the observers who have occupied themselves with an easy! and celebrated star like  $\gamma Virginis$ It is probable that more orbits have been computed for this star than for any other binary in the heavens, but as all of these are defective, according to trustworthy recent observations, a new determination of the elements based upon the best measures now available, would seem to be desirable In dealing with an orbit which has long occupied the

<sup>†</sup> Astronomical Journal, 352

<sup>‡</sup> Some of the observations here omitted are good, but in working with the graphical method I have not thought it necessary to use all of the super-abundant material

£.,

Adams, we could hardly hope for material improvement over the results already obtained, were not the investigation rendered more complete by recent observations, and by the use of the observed distances, which have generally been rejected, but which here acquire a high importance owing to the slow angular motion. The nature of the motion of  $\gamma$  Virginis is such that some of the elements, especially the periastron passage and the eccentricity, are determined with great precision; but the period has been underestimated by nearly all recent investigators, and will still remain slightly uncertain, perhaps to the extent of one year

From an investigation of the long list of observations, including the very careful measures recently secured with the 26-inch refractor of the Leander McCormick Observatory of the University of Virginia, we find the following elements of  $\gamma$  Virginia.

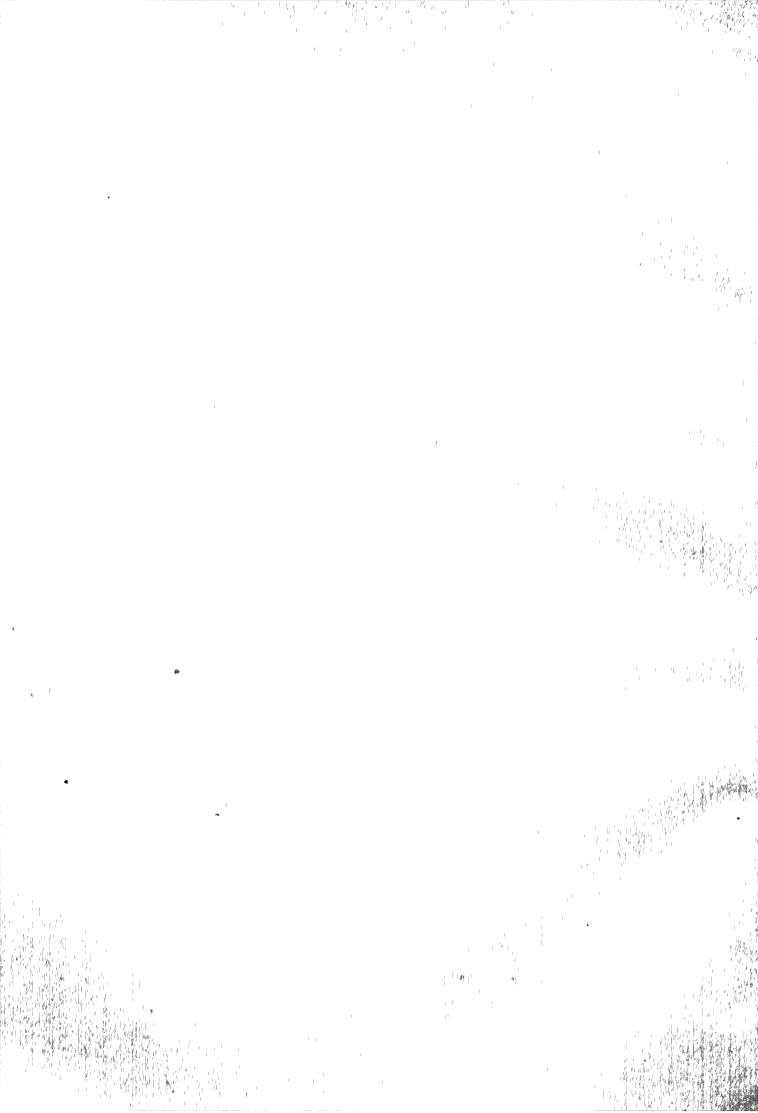

$$P = 194 \text{ 0 years}$$
  $\Omega = 50^{\circ} \text{ 4}$   
 $T = 1836 53$   $i = 31^{\circ} \text{ 0}$   
 $e = 0 8974$   $\lambda = 270^{\circ} \text{ 0}$   
 $\alpha = 3'' 989$   $n = -1^{\circ} 8557$ 

#### Apparent orbit

Length of major axis	_	6" 824
Tiong of or major axis		
Length of minor axis	=	3" 530
Angle of major axis	=	140°4
Angle of penastion		140°4
Distance of star from centre	_	3" 062

 $\gamma$  Virginis= $\sum 1670$ .

The accompanying table of computed and observed places shows that these are perhaps the most exact elements yet determined for any star. For although all the measures have not been used in forming the mean observations on which the orbit is based, yet those measures which have been employed have been so combined as fairly to represent the best material for each year. Accordingly, the residuals are uniformly small, except just before periastron passage, when the object was extremely difficult, and, as no variation of the elements will materially improve the representation of the observations in this part of the orbit without a corresponding damage elsewhere, we infer that the differences are due mainly to systematic errors in Struve's measures

It will be seen that in this orbit the line of nodes coincides with the minor axis of the real ellipse, which is also the minor axis of its projection; and owing to the small inclination the apparent ellipse is only slightly less eccentric than the real ellipse, so that the foci of the two ellipses very nearly coincide. This renders the motion of the radius vector in the apparent orbit very nearly the same as in the real orbit, and makes y Virginis an object of peculiar interest from the point of view of the study of the law of attraction in the stellar systems. From direct observation we are enabled to say that if there is any deviation from the Keplerian law of areas, it must be extremely slight. Therefore the force is certainly central, and the probabilities are overwhelming that the principal star, which is so near the focus of the apparent orbit, occupies the focus of the real orbit, or that the law of attraction is Newtonian gravitation. Other researches in double-star Astronomy increase the probability of the law of gravitation, and leave no adequate ground for doubt as to its absolute uni-Yet a prolonged study of the motion of y Virginis will eventually give a very precise criterion for the rigor of this law, as well as throw light upon the question of the existence of disturbing bodies in binary systems.

The orbit of  $\gamma$  Virginis is very remarkable for its high eccentricity, which surpasses that of any other known stellar orbit. This characteristic of  $\gamma$  Virginis, which Sir John Herschel recognized when he declared the eccentricity to be "physically speaking, the most important of all the elements" (Results at Cape of Good Hope, p. 294), seems to preclude the permanent existence of a third body in the system; for if a companion to either of the components existed, its motion would be affected by an equation of enormous magnitude, analogous to the annual equation in the moon's motion, and at the time of periastron passage would probably soon cause the body to come into collision with one of the stars, or be driven off in an orbit analogous to a hyperbola.

Thus, although the above orbit is exact to a very high degree, the system will still deserve the occasional attention of astronomers.

Since the angular motion for many years to come will be extremely slow, observations of distance will be more valuable than angular measures in effecting a further improvement of the elements.

				U				-	

Since the date of discovery this remarkable star has described almost three revolutions. From the first it was given particular attention by WILLIAM and

Otto Struve, and the peculiar and unique character of the system has fully justified the care with which it has been measured. The only previous investigation\* of the orbit is that made by Otto Struve and Dublago in 1874 (Monthly Notices 1874-5, p. 367). O Struve's elements are as follows:

$$P = 2571 \text{ years}$$
  $\Omega = 11^{\circ} 0$   
 $T = 186992$   $\iota = 90^{\circ}$   
 $e = 0480$   $\lambda = 99^{\circ} 18$   
 $a = 0'' 657$ 

Some three years ago Burnham placed at my disposal a list of measures which was nearly complete, I have since added to it such as were omitted, and besides made new observations during 1895. When scrutinized under the fine definition of the 26-inch Clark Refractor of the University of Virginia the pair proved to be excessively close, and with a power of 1300 could only be elongated. The object has now become single in all existing telescopes and can not again be separated until about 1899.

The method followed in the present investigation of the orbit is not very different from that employed by Otto Struve, except that the results are based upon the measures of all reliable observers and are rendered more complete by the observations made since 1874. The list of measures is complete to the occultation of 1896.

It will be seen from an examination of the observations that the motion is to all appearances exactly in the plane of vision, and hence with the exception of the node and inclination, the elements are based wholly on the distances. O. Struve's elements are very good, and it would therefore be sufficient to apply differential corrections to his values, but as I had independently discovered a graphical method similar to that employed by him, it seemed of interest to make use of it in deriving approximate values directly from the phenomena With the elements approximately determined, the observations furnished 52 equations of condition, which were solved for the five unknowns, the weights assigned being proportional to the number of nights. An application of the corrections resulting from the Least Square adjustment gave the following values of the elements

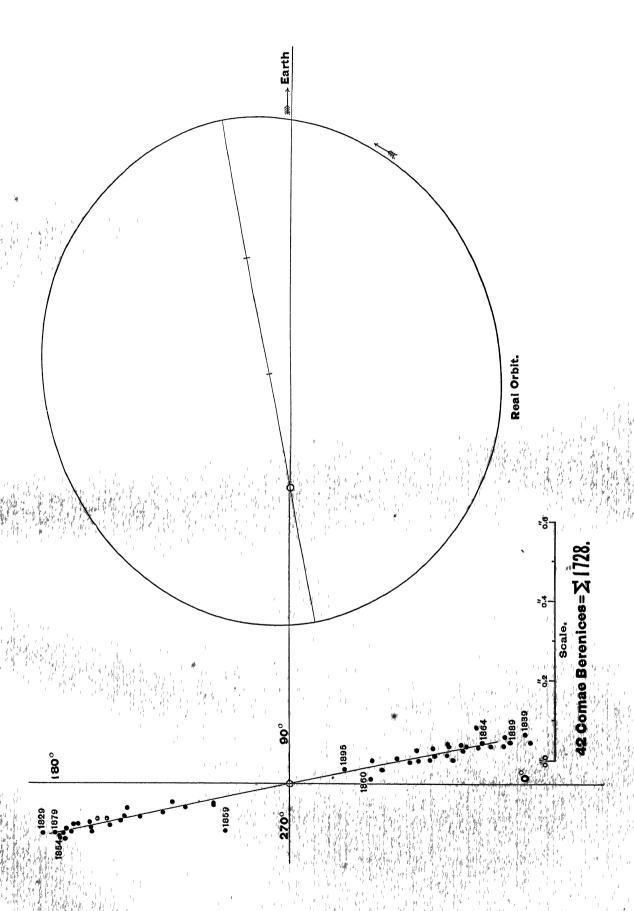

```
P = 25556 \text{ years} Q = 11^{\circ} 9

T = 188569 i = 90^{\circ}

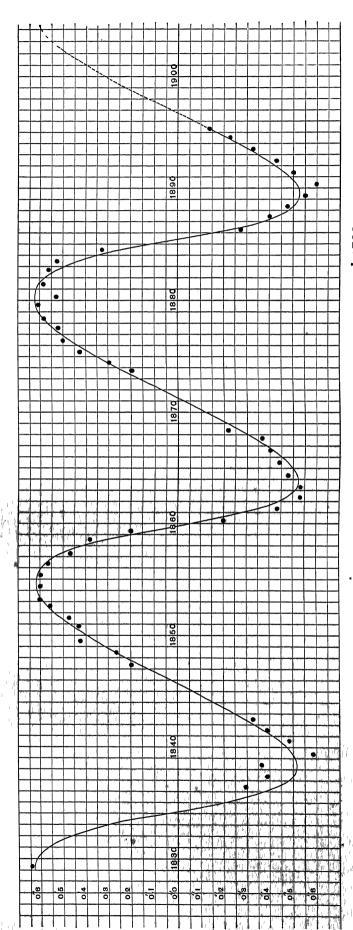

e = 0461 \lambda = 280^{\circ} 5

a = 0'' 6416 n = \pm 14^{\circ} 0867
```

<sup>\*</sup>Monthly Notices, June, 1896

Graphical Illustration of the Motion of 42 Comae Berenices =  $\sum_{i=1}^{n} |728_i|$ 

	•	
,		,

## Apparent orbit

Length of major axis	= 1'' 147
Length of minor axis	= 0'' 00
Angle of major axis	= 11° 9
Angle of penastron	$= 11^{\circ} 9$
Distance of star from centre	= 0'' 054

The apparent motion is shown in the accompanying diagram, to which is added a figure of the real orbit. A graphical illustration of the motion, obtained by taking the x-axis to represent the time, while the ordinates represent the distances, was employed in finding the approximate values of the elements, the curve here traced represents the motion according to the elements as corrected. This orbit of 42 Comae Berenices is one of the most exact of double-star orbits, and will never require any but very slight modifications. The period can hardly be in error by more than 0.1 year, while a variation of  $\pm 0.01$  in the eccentricity is very improbable.

Since the epoch of discovery in 1844 the companion has described an entire revolution, but the discordance of the observations renders it difficult to define the exact character of the orbit. The measures are frequently very inconsistent, and the most careful selections are necessary in forming the mean places. During the past few years the system has received merited attention from Burnham and Schiaparelli, their measures make known the nature of the motion and enable us to fix the elements with considerable precision. Burnham was the first to give a proper interpretation of the earlier observations (Observatory, July, 1891), and to find a satisfactory apparent ellipse. Gore afterwards attempted an investigation of the orbit based on the angles only; he found the following elements

$$P = 47.70 \text{ years}$$
  $\Omega = 51^{\circ} 93$   
 $T = 1883.12$   $\iota = 82^{\circ} 81$   
 $\iota = 0.0575$   $\lambda = 43^{\circ} 51$   
 $\iota = 0'' 58$ 

The exclusive use of angles in deriving the orbits of close and difficult double stars has frequently led to erroneous results, because when the distance is very small it is even more reliable than the angle. The use of distances becomes not only important but also necessary when the orbit is highly inclined, and the companion therefore has an angular motion which is small compared to the errors of observation, as is the case with  $0\Sigma 269$ . Accordingly in dealing with the orbit of this star we have given rather more attention to the distances than to the discordant and frequently retrograding angles. Using certain selected measures of the best observers we find the elements of  $0\Sigma 269$  to be as follows:

$$P = 48 \text{ 8 years}$$
  $\Omega = 46^{\circ} 2$   
 $T = 1882 80$   $\iota = 71^{\circ} 3$   
 $e = 0 361$   $\lambda = 32^{\circ} 63$   
 $a = 0'' 3248$   $n = +7^{\circ} 3771$ 

## Apparent orbit.

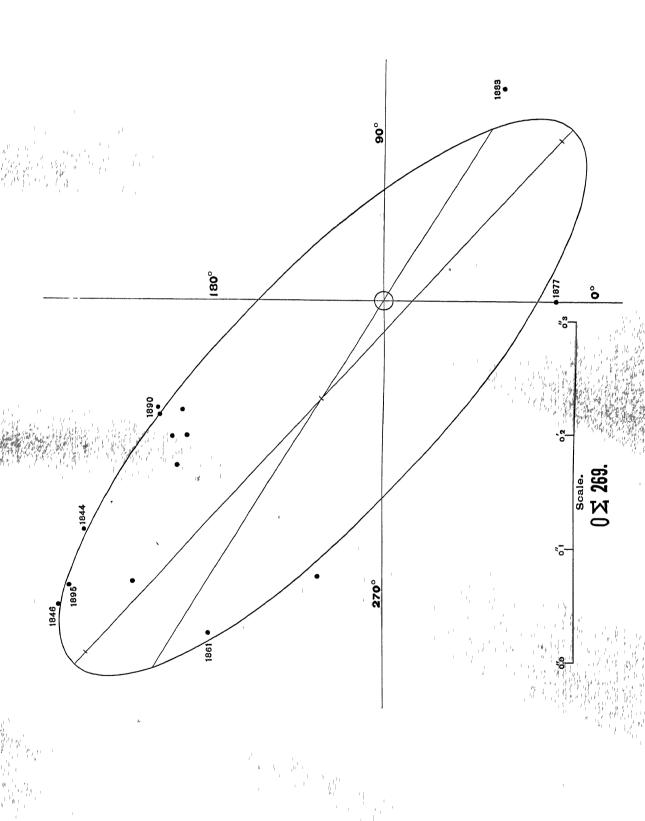

Length of major axis = 0'' 64Length of minor axis = 0'' 20Angle of major axis  $= 47^{\circ} 7$ Angle of periastron  $= 57^{\circ} 8$ Distance of star from centre = 0'' 102

The period here found is undoubtedly very nearly correct, but the otli elements are subject to greater uncertainty However, the observation Englemann in 1883 and Dembowski's estimate in 1877, establish the essent nature of the periastron end of the appaient ellipse, and assure us that large correction of our apparent orbit will ever be required The eccentiac is not likely to be altered by more than ±005, nor can the node and inclin tion suffer changes which are proportionately larger Thus it appears that 1 orbit is very satisfactory for the scant material now available, and while lat corrections are not to be anticipated, it will be desirable to improve upon the elements when more good measures are secured The ephemeris shows tl the star will be comparatively easy for a good many years, and it will the fore commend itself to the regular attention of observers

The observations of this remarkable system prior to 1840 gave evidence of a slow retrograde motion, and accordingly it received the attention of Otto Struve, Madler, Dawes, and subsequent observers. Up to this time the radius vector has swept over 308° of position-angle, while the distance has diminished from 1"13 to 0"23 and again increased to about its former value. The data furnished by observation do not suffice to fix the elements of the orbit with great accuracy, but we believe that it is now possible to get a fair approximation to the motion, and that the resulting elements will not be sensibly improved for a great many years

When the measures of this star are examined it is found that they are far from satisfactory, and therefore we must not expect an agreement such as could be obtained for easier objects, where the components are wider or more nearly equal in magnitude. Some of the recorded measures are so inconsistent that the mean places must be formed with care, and even then the representation of the motion is not entirely satisfactory The smaller distances have been under-measured, as is clear from the fact that a star of this difficulty could not be seen with small telescopes (such as those used between 1860 and 1875), unless separated by something like 0"3 Under these cucumstances it seemed proper to increase the measured distances near periastron, in order that when plotted on the diagram of the appaient ellipse they might not convey to the reader an erroneous impression. In the table of computed and observed places, however, we have retained the original values, and it will be seen that the differences are not at all considerable. Doberck is the only astronomer who has previously computed an orbit for this pair; using measures up to 1880 he found

$$P = 119 9 \text{ years}$$
  $\Omega = 42^{\circ} 4$   
 $T = 1863 0$   $\iota = 33^{\circ} 3$   
 $e = 0.72$   $\lambda = 245^{\circ} 0$   
 $\alpha = 0'' 81$ 

and the state of

A careful investigation of all the observations leads to the following elements of 25 Canum Venaticorum.

```
P = 1840 \text{ years} \Omega = 123^{\circ} 0

T = 18660 \iota = 33^{\circ} 5

e = 0752 \lambda = 201^{\circ} 0

a = 1'' 1307 n = -1^{\circ} 9565
```

## Apparent orbit

Length of major axis = 1'' 91Length of minor axis = 1'' 08Angle of major axis  $= 108^{\circ} 9$ Angle of periastron  $= 285^{\circ} 4$ Distance of star from centre = 0'' 714

This orbit is remarkably eccentric, and so far as known is surpassed in this respect by four stars only —  $\gamma$  Virginis (0.9),  $\gamma$  Andromedae (0.85),  $\gamma$  Centauri (0.80) and 99 Herculis (0.78). Whatever changes may hereafter be required in these results, it is certain that the eccentricity will remain conspicuous, and will not be varied sensibly from the value here obtained. The period, however, remains uncertain by perhaps 25 years, so that the motion of the system is not so well determined as could be desired. An ephemeris is appended for the use of observers

In attempting to investigate the orbit of a Centauri it seems desirable to review briefly the work already done on this celebrated system.

The record left us by RICHAUD does not throw much light upon the nature of the orbit, but is of considerable historical interest

"Regardant à l'occasion de la Comète plusieurs fois les pieds du Centaure avec une lunette d'environ douze pieds, je remarquai que le pied le plus oriental et le plus brillant etoit une double étoile aussi bien que le pied de la croisade; avec celte difference que dans la croisade, une étoile paraît avec la lunette notablement eloignée de l'autre; au lieu qu' au pied du Centaure, les deux étoiles paraissent même avec la lunette presque se toucher; quoique cependant on les distingue aisement."†

The next record of a Centauri was made by FATHER FEUILLÉE, who observed at Lima, Peru, July 4, 1709; in his Journal des Observations, &c., Paris, 1714, tome I, p. 425, we find the following account:

"Sur les deux heures du matin, en attendant que je pusse observer l'émersion du premier satellite de Jupiter, que des nuages me cachèrent, j'observai avec une lunette de 18 pieds l'étoile de la premier grandeur qui est au pied boréal du devant du Centaure, je trouvai cette étoile composée de deux, dont l'une est de la troisième grandeur et l'autre de la quatrième. Celle de la quatrième grandeur est la plus occidentale, et leur distance est égale au diamètre de cette étoile"

From this rather indefinite observation Powell infers that the distance of the components in 1709 was about 10", and attaches considerable importance to the remark that the companion was "the more westerly" (la plus occidentale) Unfortunately the language is rather ambiguous, and we can not tell whether Feuillée meant that the companion was really to the west of the central star, or whether it merely appeared to the west in the inverted field of view. As

<sup>\*</sup> By photography

<sup>†</sup> Publications of the Royal Academy of Sciences, Paris, 1692, or Monthly Notices, 1884-5, p 18

a Centauri was low in the southwest when the observation was made, it is also possible that the remark may have arisen, as Mr Roberts has observed, from the position of the heavens at that instant rather than the position-angle of the companion. In any case it follows from the orbit here deduced that the position-angle was 24°3, and the distance 10″.07

The third observation of a Centauri was made by Lacaille at the Cape of Good Hope in 1752. While determining the positions of southern stars he observed the components of a Centauri, and from the resulting  $\Delta a$  and  $\Delta \delta$  we find the values of  $\rho$  and  $\theta$  given in the list of measures. The observations of Lacaille were first printed in the Cælum Australe Stelliferum, which was published at Paris in 1763, and reprinted in 1847 by the British Association for the Advancement of Science, under the auspices of a Committee composed of Herschel, Henderson and Bailly. Lacaille's observations appear to be as good as could be expected from the instruments and methods employed.

In 1761 a Centauri was observed on one night by Maskelyne while at the island of St Helena, by means of a rough divided-object-glass microineter he found a distance of 15" 6

The observations made early in the present century by Fallows, Brisbane, Dunlop, Johnson, Taylor and Henderson, rest on measures of  $\Delta a$  and  $\Delta \delta$ The observation of Fallows was made with a small and defective Altitude and Azimuth Instrument, and is entirely enoneous For a long time this measure was very misleading to computers, as it indicated an eccentricity of about ()96 The results of Brisbane, Dunlop, Johnson, Taylor and Henderson are likewise unworthy of any high degree of confidence The first observations of conspicuous worth are the micrometrical measures made by Sir John Herschel at the Cape of Good Hope The measures of Herschel taken in conjunction with others recently made expressly for the purpose have enabled us to determine the orbit of a Centauri with a degree of precision which appears extraordinary when we consider the character of the observations It will be found on inspecting the list of measures that many of them are vitiated by sensible errors of observation, which are partly systematic and partly accidental must remember, however, in judging of the value of results that a Centauri is a very bright star, so that the images are unusually large, and hence if the telescope is not practically perfect, and the atmospheric conditions favorable, we could hardly expect that the measures will be very accordant. It is also to be remembered that the southern observers are not specialists in double-star work, and hence we can not expect results such as could be obtained by the skill of a Burnham or a Struve Nevertheless, the measures of a Centuur taken as a whole, will enable us to obtain one of the best orbits yet deduced for any binary, and we may gratefully acknowledge our deep obligation to the southern observers, who amid many difficulties have measured this star with care and assiduity

In the list of measures given above will be found all the records which are of any value. The observations of T. Maclear, G. Maclear and W. Mann, which were made about the middle of the century, are taken from Dr. Elkin's Inaugural Dissertation, in which they were first printed; the number of nights was kindly supplied by Dr. Elkin in a private letter. Most of the other measures are taken from the Memoirs and Monthly Notices of the Royal Astronomical Society. In this connection I take occasion to acknowledge my special obligations to Messrs. Tebbutt, Pickering, Douglass, Russell, Sellors, Gill and Finlay for securing sets of measures expressly for this investigation, also to thank Herr Hans Ludendorff of the Royal Observatory, Berlin, for confirming from original sources the measures of Lacaille, Brisbane, Dunlor and Johnson.

Most of the orbits determined before 1875 have now only historical interest, and among those more recently determined only three are approximately correct; namely, those of Roberts (A.N., 3175), See (M.N., Dec., 1893), and Doberck (A.N., 3330). The following table of the elements found by previous computers is essentially complete:

In dealing with this orbit it seems probable that the graphical method will be superior to any process involving a least-square adjustment, because of the undoubted existence of sensible systematic errors in the observations. An adjustment based on both angles and distances will eventually be desirable, but before this definitive determination can be made with advantage, it will be necessary to have an additional revolution. In the present state of the observations it is wholly useless to apply corrections of a very minute character Basing the work upon all the best observations we find the following elements of a Centauri:

```
P = 811 years
                                               \Omega = 25^{\circ}15
                                                i = 79^{\circ}30
                         T = 187570
                                                \lambda = 52^{\circ} 00
                         e = 0.528
                         a = 17''70
                                                n = +4^{\circ}438954
Apparent orbit
                        Length of major axis
                                                       = 32'' 18
                                                       = 6'' 16
                        Length of minor axis
                                                       = 27^{\circ} 25
                        Angle of major axis
                        Angle of penastion
                                                       = 38^{\circ} 65
                        Distance of star from centre = 5" 90
```

If we adopt the parallax of GILL and ELKIN (0"75), we find that the major semi-axis of the orbit is 236 astronomical units. It follows that the combined mass of the components is 200 times the mass of the sun and earth

Thus we see that the companion of a Centauri moves in an orbit with a major axis which is about a mean between those of Uranus and Neptune But owing to the eccentricity of the orbit the distance at periastron (112) only slightly surpasses that of Saturn from the sun, while at apastron it extends considerably beyond Neptune (36.0)

According to preliminary researches of Stone in 1875, it was found that the masses of the two components are sensibly equal. Mr A. W ROBERTS has

*O*Σ'285. 149

recently made a very careful determination of this mass-latio, and finds (AN, 3313) that the masses of  $a^2$  and  $a^1$  (the companion) are as 51  $49 \pm {}_{5}^{1}$ 0 of the amount A very similar result was obtained by Dr. Elkin in his *Inaugural Dissertation*, and hence we may conclude that in this case the relative masses are known with almost the desired precision

Mr. Roberts has also made a careful discussion of the parallax of a Centauri from the meridian observations of 1879–81 and obtained (A N, 3324) results which confirm the work of Gill and Elkin with the heliometer Using both right ascensions and declinations Mr Roberts finds

$$\pi = \pm 0'' 71 \pm 0'' 05$$

Our knowledge of this system is therefore far more accurate than that of any other system in the heavens, and it does not seem possible that the results here obtained will ever be sensibly altered. But as some refinement is still possible this glorious object will always ment the attention of observers.

\* j.

 $0\Sigma 285$ .

This close double star was measured by Otto Struve several times during the few years following its discovery \* The other early measures were by Madler and Secchi, while in later years the pair has been measured only by Englemann, Schiaparelli, Burnham and the writer. Thus, only a small number of observations are available for the determination of an orbit, but it happens that these are distributed so as to give a fairly good set of elements.

The star has always been a difficult object, and hence the measures are necessarily less accurate than in case of easier pairs Burnham was the first to attempt an investigation of the orbit (Sidereal Messenger, June, 1891) His apparent ellipse and the resulting elements are not very different from those found in this paper. Mr. Gore has since attempted an orbit by a very different process, and obtained results of a wholly different character (Monthly Notices, April, 1893). These two sets of elements are.

Gore	BURNHAM
P = 11857  years	621
T = 1881 93	18853
e = 0.58	0.429
a = 0'' 46	0″ 387
$\Omega = 107^{\circ} 0$	<b>54°</b> 3
$i = 45^{\circ} 7$	<b>44°</b> 3
$\lambda = 161^{\circ} 4$	180° 0

Using all the measures, and basing the work on both angles and distances, I find the following elements of  $0\Sigma 285$ :

P = 7667 years	$\Omega = 62^{\circ} 2$
T = 188253	$i = 41^{\circ} 95$
e = 0.470	$\lambda = 162^{\circ} 23$
a = 0'' 3975	$n = -4^{\circ} 6953$

#### Apparent orbit:

```
Length of major axis = 0'' 788

Length of minor axis = 0'' 522

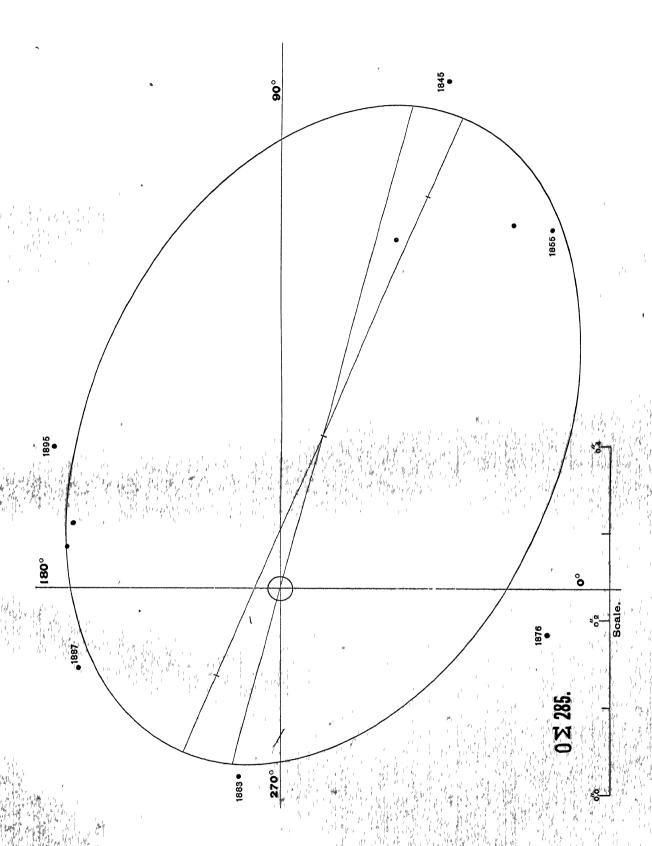

Angle of major axis = 67^{\circ} 1

Angle of periastron = 255^{\circ} 3

Distance of star from center = 0'' 182
```

The following table of computed and observed places shows that the measures are represented as well as could be expected in the case of an object of this difficulty.

<sup>\*</sup>Astronomical Journal, 356

The only large residual is that of Englemann, whose small telescope would necessarily render his observations subject to considerable uncertainty. Indeed, he gives the angle as 78°3, but I have assumed that he really saw the companion, and have therefore changed the angle by 180°. The estimate of 36° for the position-angle in 1865.53 is very hearly correct, and leaves no doubt that the elongation observed by Dembowski was real.

When I measured the object recently with the 26-inch refractor of the Leander McCormick Observatory in Virginia, the stars were not separated, except on one night, and hence the difficulty of the pair will doubtless account for the error in angle. The star is slowly separating, and ought to be observed annually. The following is an ephemeris for the next five years

t	$\theta_c$	$\rho_c$	$oldsymbol{t}$	$\theta_c$	$\rho_c$
	0	"		0	<i>II</i>
$1896 \ 40$	$135\ 6$	0 30	<b>1</b> 899 <b>4</b> 0	$122\ 3$	0.35
1897 40	130 7	0.32	<b>1</b> 900 <b>4</b> 0	118 4	0 36
1898 40	126 5	0 33			

The comparatively long period of this close star may probably be construed to mean that the system is very remote from the *Earth*, otherwise the mass would be excessively small. The eccentricity of the orbit is fairly well defined, and is near the mean value of this element among double stars.

# $\xi BOOTIS = \Sigma 1888.$

The stars of this system are somewhat unequal in magnitude, and are moreover distinguished by very striking colors. The principal star is yellow, while the companion is reddish purple; and hence the appearance of the system, so far as it depends on contrast in color and inequality of the components, is very similar to those of 70 Ophruchi and  $\eta$  Cassiopeae.\* The early observations of Herschel established the physical connection of the stars, and since the time of Struve the measures are both sufficiently numerous and sufficiently exact to give the position of the companion with the desired precision. In spite of the fact that since 1780 an arc of only about 170° has been described, we are enabled by the favorable shape of this arc to make a very satisfactory determination of the elements. The companion is now approaching periastron, and in the course of a few years the motion will become very rapid. For the next fifteen years this system will deserve special attention from observers, as the part of the apparent ellipse swept over by the companion during this interval

<sup>\*</sup> Astronomische Nachrichten, 3334

will be the most critical, and measures secured near periastron will enable us to render the orbit exact to a very high degree.

The following table gives the elements of this interesting system published by previous computers:

P	T	e	а	δ	ı	λ	Authority	Source
117 14 160 695 168 91 140 64 127 97 127 35	1779 958 1761 71 1779 75 1767 76 1770 44 1770 69	0 59374 0 454 0 7822 0 641 0 6781 0 7081	12 56 5 591 9 95 5 425 4 813 4 86	0 0 172 7 11 4 11 6 12 02 26 37		101 0 315 2 96 4 124 15 130 9 117 77	Mädler Hind, 1872	

From an investigation of all the observations we are led to the following elements of  $\xi$  Bootis:

$$P = 128 \text{ 0 years}$$
  $\Omega = 10^{\circ} \text{ 5}$   
 $T = 1903 \text{ 90}$   $\iota = 52^{\circ} 28$   
 $e = 0.721$   $\lambda = 239^{\circ} 25$   
 $a = 5'' 5578$   $n = -2^{\circ} 8125$ 

### Apparent orbit:

Length of major axis = 9''.07Length of minor axis = 5''.76Angle of major axis  $= 167^{\circ}.7$ Angle of periastron  $= 144^{\circ}.7$ Distance of star from centre = 2''.94

					<u> </u>			1

The table of computed and observed places shows that the set of elements given above is extremely satisfactory, and we may confidently conclude that the general nature of the orbit here obtained will never be materially changed.

It is possible that the period may be varied by so much as one year, and that the eccentricity is uncertain to the extent of about  $\pm 0.02$ ; larger alterations in these quantities are not to be expected, and the values of the other elements are correspondingly well determined

The system of \(\xi\) Boots is chiefly remarkable for the great eccentricity of the orbit, and for the wide angular separation of the components. The great length of the major-axis and the comparatively short periodic time would support the belief that the system is not very far from the earth, and this view of relative proximity is rendered the more probable by the brightness of the components. But while these considerations tend to render it probable that the parallax is sensible, such a view is not supported by the small proper motion of the system in space, which is only 0"161 per year. We might, therefore, infer that the system is perhaps very remote from the earth, and hence of enormous dimensions, or comparatively near us, with the proper motion mainly in the line of sight. In any case the parallax of this system is particularly worthy of investigation, and it might be determined either by the ordinary process of direct measurement, or by the spectroscopic method (A.N., 3314, or \§5, Ch I), which here seems likely to be entirely practicable.

The following is an ephemeris for the companion for the next ten years:

t	$\theta_{o}$	$ ho_{\sigma}$	t	θ,	p,

This beautiful pair proved to be one of the first objects which gave distinct evidence of orbital motion, and the binary character of the system was fully recognized by Herschel in 1803. Since the time of Struve the measures are both numerous and satisfactory. The pair is always rather close, but as the components are nearly equal in magnitude, it is generally easy to separate. Numerous orbits have been published by previous computers; the following table of elements is fairly complete

Making use of all the measures up to 1895, we find the following elements of  $\eta$  Coronae Borealis\*:

$$P = 41 60 \text{ years}$$
  $\Omega = 27^{\circ} 10$   
 $T = 1892 50$   $\iota = 58^{\circ} 50$   
 $e = 0 267$   $\lambda = 217^{\circ} 57$   
 $\alpha = 0'' 9165$   $n = +8^{\circ} 653846$ 

### Apparent orbit:

```
Length of major axis = 1'' 804

Length of minor axis = 0'' 934

Angle of major axis = 28^{\circ} 7

Angle of periastron = 229^{\circ} 0

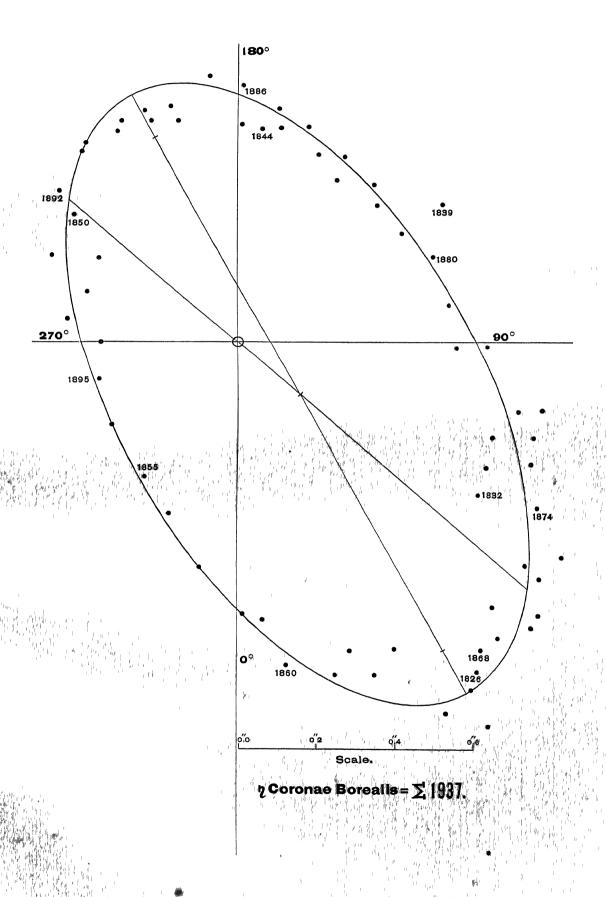

Distance of star from center = 0'' 209
```

The accompanying table shows that the motion is well represented, and that the present elements will finally undergo but slight corrections.

The uncertainty in the period does not surpass 0.1 year, and an alteration of the eccentricity amounting to  $\pm 0.01$  is not probable. It seems, however, that there are occasional systematic errors in the angles, and hence careful measurement should be continued. It will not be many years before a definitive determination of the elements of this interesting binary can be advantageously undertaken. The following is a short ephemens for the use of observers

When the observations of 1782 were compared with those of 1802, the physical character of the system was fairly indicated \* Since the time of Struve it has been carefully followed by the best observers, and accordingly the material now available for an orbit is highly satisfactory. The companion is only slightly smaller than the principal star, and is therefore never very difficult to measure. In all parts of the orbit the pair is sufficiently wide to be seen with a six-inch telescope, but as the minimum distance of 0"49 in angle 230° was passed in 1858, it is not surprising that the observers on either side of this epoch, with few exceptions, have made their observed distances too small. Thus, although the measures of different observers are not infrequently affected by systematic errors of sensible magnitude, yet by combining the best measures into mean positions for each year, we obtain a set of places which give an orbit that seems likely to be very near the truth

Some of the elements hitherto published are as follows

P	T	e	а	ಬ	ı	λ	Authority	Source
146 649 182 6 314 34 200 4 198 93 290 07 280 29 266 0	1851 57 1866 0 1860 88 1865 2 1865 5 1863 51 1860 51 1862 55	0 8529 0 491 0 5641 0 51 0 4957 0 6174 0 5974 0 5668	1 320 1 165 1 761 — 1 500 1 47 1 057	94 7 166 1 163 2 172 0 169 0 183 0 173 7 166 7	49 4 47 5 41 9 45 0 46 4 44 4 39 9 35 2	87 1 23 0 54 4 20 1 23 6 17 7 20 0 40 9	Wilson, 1872	M N ,vol XXXII,p 250 Handb D S , p 313 Handb D S , p 313 A N , 2026

From an investigation of all the observations which appear to be reliable, we find the following elements of  $\mu^2$  Bootis:

$$P = 219 \ 42 \ \text{years}$$
  $\Omega = 163^{\circ} \ 8$   
 $T = 1865 \ 30$   $i = 43^{\circ} \ 9$   
 $e = 0537$   $\lambda = 329^{\circ} \ 75$   
 $\alpha = 1'' \ 2679$   $n = -1^{\circ} \ 6407$ 

### Apparent orbit:

```
Length of major axis = 2'' 656

Length of minor axis = 1'' 480

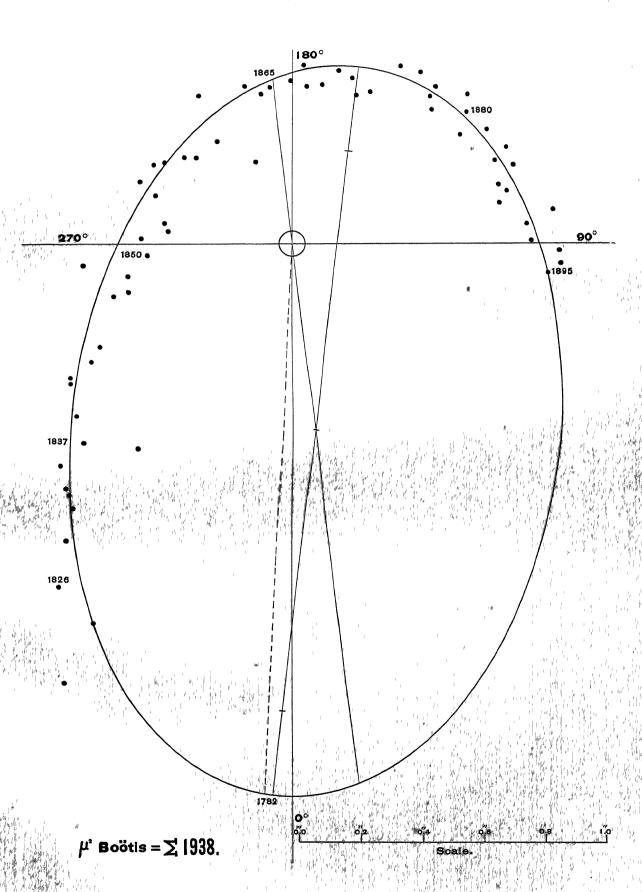

Angle of major axis = 173^{\circ} 5

Angle of periastron = 186^{\circ} 7

Distance of star from centre = 0'' 638
```

An examination of the computed and observed places, given in the following table, seems to justify the conclusion that the elements found above will

<sup>\*</sup>Astronomische Nachrichten, 3309

	•	
	,	

not be materially changed by future investigation. Thus, the period will hardly be varied by so much as ten years, while the resulting alterations in the eccentricity, inclination and other elements will be relatively inconsiderable.

Since the discovery of this binary in 1845, the companion has described substantially an entire revolution. The period is therefore fixed with sufficient precision; indeed, the numerous and satisfactory measures of this pair secured during the last fifty years define the other elements in a manner almost equally satisfactory. The shape of the apparent orbit is such that the pair is never excessively difficult, and yet measurement near periastron, where the distance reduces to 0"22, requires a good telescope. The components are of nearly equal brightness, and hence a number of the measures as recorded requires a correction of 180°

The following orbits of this pair have been published by previous computers:

P	T	е	a	ಬ	i	λ	Authority	Source

The table of computed and observed places shows that these elements are extremely satisfactory. Future observations are not likely to vary the period given above by more than one year, while an error of  $\pm 0.02$  in the eccentricity is highly improbable. In spite of the accuracy of the present elements some improvement will ultimately be desirable, and hence astronomers should continue to give this interesting system regular attention. The star will be easy

*

for a number of years, and observers with small telescopes will find it an important object for measurement.

The following is a short ephemeris.

The components of this remarkable system are of the 4th and 7th magnitudes, and of yellow and bluish colors respectively, so that the object is generally very difficult Struve happened to discover\* the companion near the time of its maximum elongation, when the polar coordinates were  $\theta = 111^{\circ}$ 0,

<sup>\*</sup> Astronomical Journal, 376

 $\rho = 0^{\circ}$  72. Measures in 1828, 1831 and 1833, showed that both angles and distances were steadily decreasing, and in 1835 the star appeared single under the best seeing. The companion was not again recognized with certainty until 1842, although STRUVE, O. STRUVE and MADLER searched for it repeatedly during the intervening period, and occasionally suspected an elongation discordance in the angles of the supposed elongations justify the belief that the phenomena observed were probably nothing more than points of diffraction fringes, or some other kind of spurious images. Madler's observation of 332° 3 and 0".18 at the epoch 1841 50 may be genuine, although at this time the star The binary character of the pair was early must have been excessively close recognized by STRUVE, who pointed out the particular interest attaching to the system on account of its high inclination. Y Coronae Borealis has since been measured by many of the best observers, and yet the stars are so unequal and so close that the errors of observation assume formidable proportions, and render a satisfactory determination of the elements very difficult inclination of the orbit throws nearly all the position-angles into small regions of about 10° on either side, and while the retrograde motion ought to make all angles steadily decrease, we are sometimes confounded by an appearance of direct motion (as from 1859 to 1863) which proves the existence of sensible systematic errors, probably due to the placing of the micrometer wires parallel to the edges of unequal images.

It is equally confusing to find that instead of a steady increase and decrease in the distance, nearly all of the distances are in the immediate neighborhood of 0".4, such measures are of course misleading, as the companion cannot be standing still at a constant angle and distance. While, therefore, it is clear that the elements can not lay claim to such accuracy as could be desired, it will yet appear that they are good and even excellent for observations which are so badly vitiated by accidental and systematic errors

It is obvious that in case of a system whose orbit plane lies nearly in the line of vision, the angles will be practically useless unless measured with the greatest accuracy, yet, in this instance, even when the pair is fairly wide, we frequently find the angles of individual observers differing by so much as 10°, and when the stars are close the uncertainty in angle will amount to at least twice this quantity. On account of such conspicuous errors in angle we have based the present orbit largely upon the distances.

DOBERCK and CELORIA are the only astronomers who have previously attempted an orbit for this pair.

From an investigation of the best observations we find the following elements.

$$P = 730 \text{ years}$$
  $\Omega = 110^{\circ} 7$   
 $T = 18410$   $\iota = 82^{\circ} 63$   
 $e = 0.482$   $\lambda = 97^{\circ} 95$   
 $a = 0'' 7357$   $n = -4^{\circ} 9315$ 

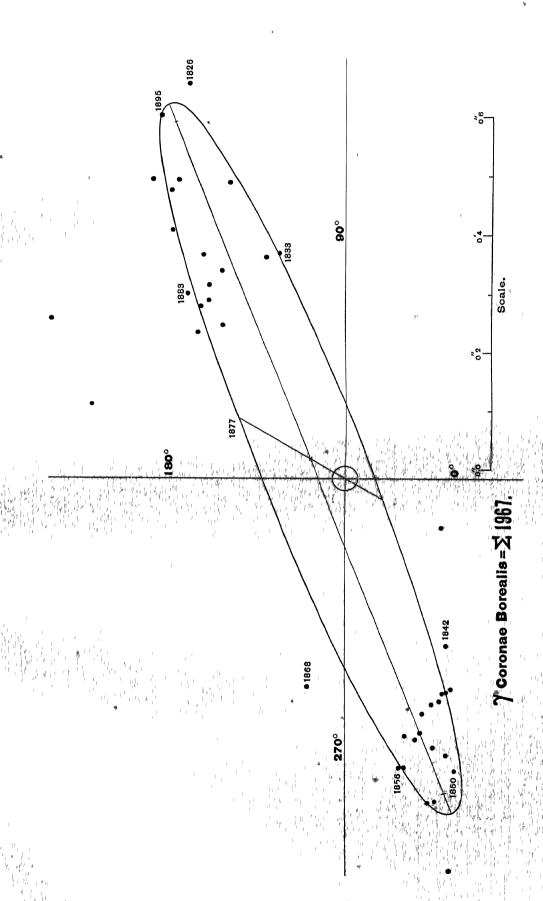

### Apparent orbit

Length of major axis = 1'' 30Length of minor axis = 0'' 175Angle of major axis  $= 111^{\circ} 3$ Angle of periastron  $= 329^{\circ} 6$ Distance of star from centre = 0'' 068

The accompanying table shows the agreement of the above elements with the mean places.

According to this orbit previous investigators have materially overestimated the period. While the time of revolution must at present remain slightly uncertain, it does not seem at all probable that this element can surpass 75 years. It follows, therefore, that  $\gamma$  Coronae Borealis belongs to the class of unequal binaries with moderately short periods. The inclination and line of nodes here obtained will probably be nearly correct, while the eccentricity is not likely to be varied by so much as  $\pm 0.05$ .

Recent distances have been appreciably undermeasured by several observers; the separation of the components is now about 0".68, and will not change sensibly for several years.  $\gamma$  Coronae Borealis needs further observation, and astronomers should continue to give it regular attention; but owing to the peculiar shape of the apparent orbit great care must be exercised to avoid systematic errors, if the measures are to be of much value in effecting a further improvement of the elements.

# $\xi$ SCORPII = $\Sigma$ 1998.

This bright star has been observed with considerable regularity since the time of Struve, and much material is now available for the investigation of its orbit. But while the measures are numerous, the considerable southern declination of the object renders them rather difficult, especially for European observers, and hence there is reason to suppose that the results are not free from systematic errors. In the investigation of the orbit we have adopted the usual method, depending on both angles and distances, and, as in case of \(\zeta\) Cancri, have neglected the influence of the third star. This procedure has been adopted by Dr. Schorr in his Dissertation on the motion of this system, and is fully justified by the rough and somewhat unsatisfactory state of the measures, which will not yet permit any very fine \*determination of the elements. Several computers have previously worked on the motion of this system; the following list of orbits is believed to be fairly complete.

P	T	e	a	Ω	ı	λ	Authority		Source
49 048 95 90	1832 611 1860 59 1859 62 1862 32	 0 0768 0 122		1127 $1225$		78 57	Doberck,	1877	AN, 1199 AN, 2121 Dissertation, Munich

We find the following elements

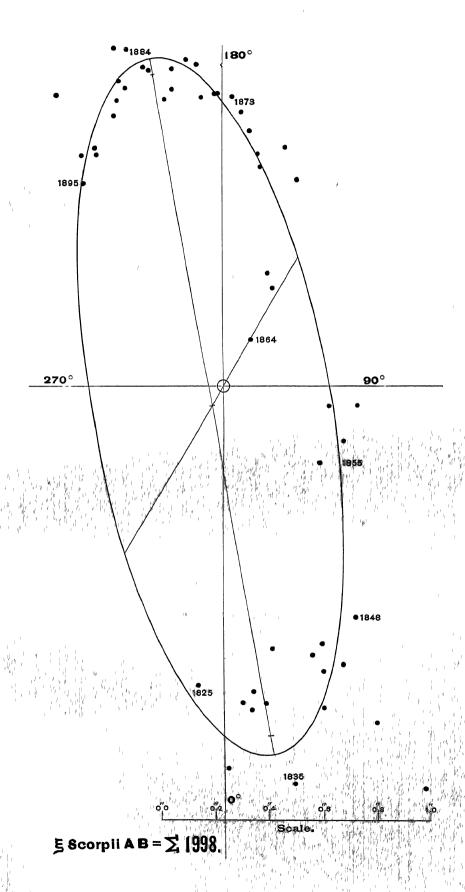

$$P = 1040 \text{ years}$$
  $\Omega = 9^{\circ} 5$   
 $T = 186460$   $\iota = 70^{\circ} 3$   
 $e = 0.131$   $\lambda = 111^{\circ} 6$   
 $\alpha = 1'' 3612$   $n = +3^{\circ} 4616$ 

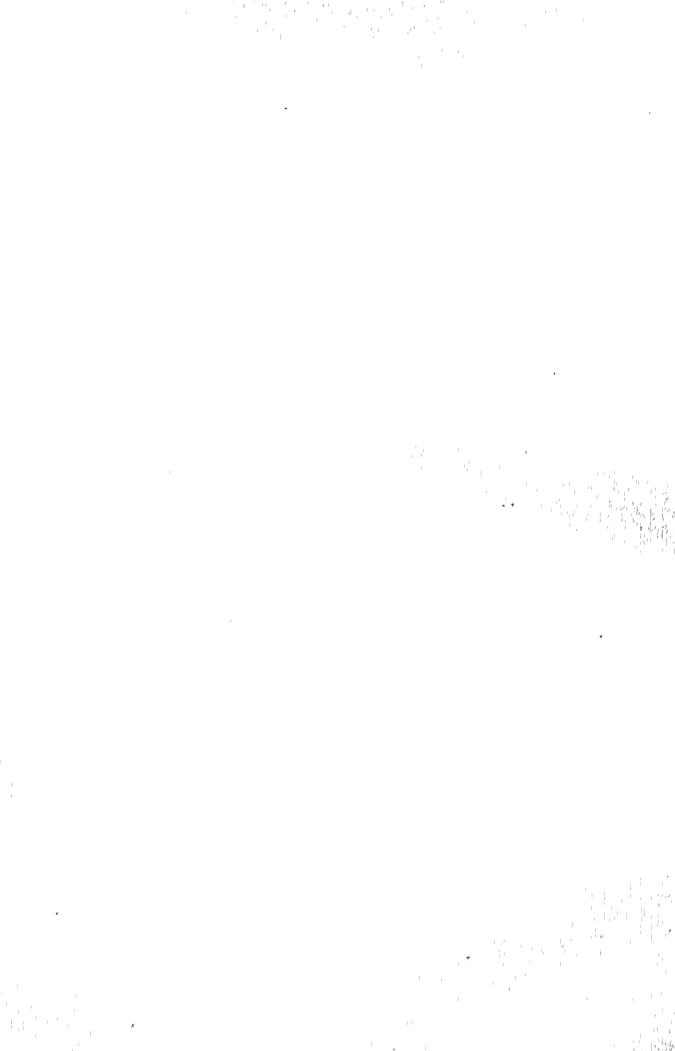

Apparent orbit:

Length of major axis = 2'' 696Length of minor axis = 0'' 884Angle of major axis  $\cdot = 9^{\circ} 6$ Angle of periastron  $= 150^{\circ} 2$ Distance of star from centre = 0'' 085

The table of computed and observed places shows a very satisfactory agreement, and we may conclude that no very considerable alteration is likely to be made in these elements. But the orbit is so nearly circular and so highly inclined that the definition of  $\lambda$  is not very exact, and in case of this element a larger alteration may be found necessary, when the material shall be sufficient for a definitive determination.

The small eccentricity of this orbit is rather remarkable. Among known binaries there are very few which have such circular orbits,  $\delta$  Equuler,  $\Sigma$  2173 and  $\mu$  Herculis being the principal objects of this kind, and as most of these orbits are highly inclined, there is still some uncertainty attaching to the eccentricity. It will be necessary to have more exact observations of these stars in

critical parts of their orbits before this element can be defined with the desired precision

COMPARISON OF COMPUTED WITH OBSERVED PLACES

Since Herschel's discovery of this star the companion has described an arc\* of 223°. The shape of this arc is such that it fixes the apparent ellipse with considerable precision, and enables us to obtain a set of elements which will never be radically changed. It is singular, however, that the periods heretofore obtained for this star are very discordant, and in several instances more than double that found below. Such extraordinary divergence of results may be explained by the lack of sufficient curvature in the arc swept over by the companion at the time the earlier elements were derived, and by the use of injudicious methods in the determination of the orbit

In this as in most other cases the graphical method based on both angles and distances is superior to analytical methods, and at once enables us to trace the apparent ellipse with the necessary precision. The following table gives a complete summary of the elements found by previous computers who have worked on the motion of this interesting binary.

Making use of all the observations up to 1895 we find the following elements:

$$P = 3700 \text{ years}$$
  $Q = 30^{\circ} 5$   
 $T = 182180$   $i = 47^{\circ} 48$   
 $e = 0540$   $\lambda = 47^{\circ} 7$   
 $a = 3'' 8187$   $n = +9^{\circ} 7297$ 

<sup>\*</sup>Astronomische Nachrichten, 3339

## Apparent orbit

```
Length of major axis = 7'' 08

Length of minor axis = 4'' 71

Angle of major axis = 42^{\circ} 4

Angle of periastron = 66^{\circ} 9

Distance of star from centre = 1'' 735
```

There is of course some uncertainty attaching to a period of such great length, but careful consideration of all possible variations of the apparent ellipse convinces me that the value given above is not likely to be varied by more than 25 years, and a change of twice this amount is apparently impossible. The eccentricity is very well determined, and a change of  $\pm 0.04$  in the above value is not to be expected

The distance of the components of  $\sigma$  Coronae Borealis is now so great that the companion will move very slowly for the next two centuries. Therefore, so far as the orbit is concerned observations of the pair will be of small value, as very little improvement can be effected for a great many years, but it may still be worth while to secure careful measures of the system, with a view of establishing the regularity of the elliptical motion, and the absence of sensible disturbing influences. There are no irregularities in the measures heretofore secured which are not attributable to errors of observation. The table of computed and observed places shows an agreement which is extremely satisfactory.

SIR WILLIAM HERSCHEL made his first measure of this star, July 21, 1782, and found the position-angle to be 69°.3 \*

In 1795 he again examined the object, and noted that the distance had

<sup>\*</sup> Astronomical Journal, 357

decreased, but that it was in the same quadrant as before; this appears, however, to be a mistake, as the companion at that time must have been in the opposite quadrant. It is remarkable that Herschel could not separate the companion in 1802, as the angle was then 174°5, and the distance 1".24.

Beginning with STRUVE's observation in 1826 the record is practically continuous, and we have measures for each year, except when the companion was so close as to be lost in the rays of the larger star

The periastron is so near the central star, on account of the considerable eccentricity and the position of the node, that the companion has never been seen in this part of the orbit. According to the elements found below, the minimum distance is about 0".45. Therefore, in spite of the comparative faintness of the companion, whose magnitude is 6.5, while that of the central star is 30, this object ought to be constantly within the reach of our great refractors. In previous revolutions, however, the star has been lost, and it will therefore be a matter of great interest to follow it during the next periastron passage in 1899. Good observations in this part of the orbit are needed, and the rare phenomenon which will be presented by  $\zeta$  Herculus about the end of this century will be worthy of the attention of observers with large telescopes.

Notwithstanding the three revolutions which have been completed since Herschel's discovery in 1782, our knowledge of the orbit of this pair has remained somewhat unsatisfactory; the elements heretofore obtained are by no means accordant. This divergency of results may be attributed partly to errors of observation incident to the inequality of the components, and partly to a sensible mistake in the old position-angle of Herschel, which ought to have been about 80°. Indeed, Herschel's observation does not seem to lay claim to much accuracy, for on August 30, 1782, he says. "Saw it better than I ever did,"—implying that on the previous occasions the companion was not very well defined. The following table gives the elements published by previous investigators:

P	T	e	a	Ω	i	λ	Authority	Source

34.4 34 411	1864 8 1864 78	0 463 0 4666	1 284 1 345	41 73 44 1	43 23 44 53	$\begin{vmatrix} 252 & 75 \\ 251 & 8 \end{vmatrix}$	Doberck, 1880 Doberck	A N ,2332

After an examination of all the observations we formed mean positions for each year, and from these mean places deduced the following elements.

```
P = 35\,00 \text{ years} \Omega = 37^{\circ}5

T = 1864\,80 \iota = 51^{\circ}77

e = 0\,497 \lambda = 101^{\circ}7

a = 1''\,4321 n = -10^{\circ}2843
```

## Apparent orbit

```
Length of major axis = 2'' 492

Length of minor axis = 1'' 752

Angle of major axis = 43^{\circ} 1

Angle of periastron = 289^{\circ} 0

Distance of star from center = 0'' 455
```

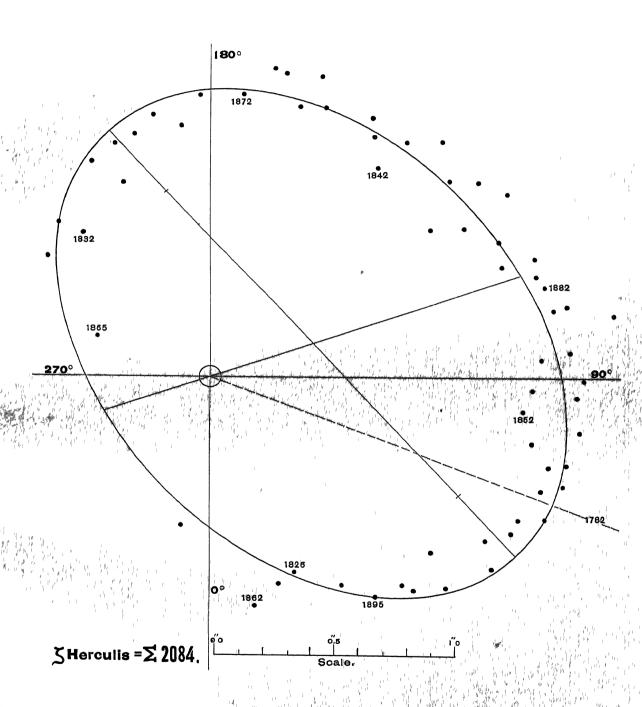

The following table of computed and observed places shows that the elements give a good representation of the observations, and render it probable that the present orbit is very near the truth. There are some errors in the position-angles which appear to be systematic, and we have not been able to improve the representation, for whatever would improve the agreement in one place would injure it in another, or in the same place during the next revolution

ŧ

It will be seen that this orbit is slightly more eccentric than most of those heretofore deduced, but it is not probable that the eccentricity will prove to be too large. If any change should be required in this element, it is likely to increase rather than diminish the value given above. The eccentricity of the orbit of  $\zeta$  Herculis is near the mean value of this element among double stars.

The companion is worthy of regular attention in the part of the orbit now being described, but observation will become more urgent as the star approaches periastron in 1899. If good observations can be secured they will enable us to give the highest precision to the theory of the motion of this star; but if the measures in so delicate a case are affected by sensible systematic errors they

will prove to be of little value. The phenomena of the approaching appulse of  $\zeta$  Herculis will therefore be difficult to observe, and results of importance can only be obtained by skillful treatment. It is hardly necessary to add that this phenomenon will not again be witnessed for more than a third of a century.

It seems worthy of remark that STRUVE, who devoted so much attention to the colors of double stars, noted the color of the companion as reddish, while it is now distinctly bluish, and although a change of color does not seem probable, this has been suspected as well as variability

In order that astronomers may be able to compare the present theory with observations during the rapid motion of the companion in passing periastron, we give an epheneris for the next ten years

Since the discovery of this rapid binary the companion has described an arc of 280°. The magnitudes of the components are 64 and 78 respectively, and as the pair is never closer than 0″58 the object is difficult only on account of its southern declination.\* The period is surprisingly short for a system of

<sup>\*</sup>Astronomical Journal, 872

such considerable separation, and this circumstance lends decided probability to the view that the parallax is sensible Provisional elements for this system have been computed by Glasenapp, Gore and Burnham. Their results are as follows:

P	T	е	а	ಬ	ı	λ	Authority	Source
34 88 34 48 24 7	1891 85	0 556	2 13	139 4	567	278 2	Gore, 1893	Astron and Astroph, May, 1893 Monthly Notices, Maich, 1893 Publ Lick Obs, vol II, p 247

The observations which I secured recently at the Washburn Observatory have enabled me to redetermine the orbit. Using all available measures, we find the following elements of  $\beta$  416.

$$P = 330 \text{ years}$$
  $\Omega = 144^{\circ} 6$   
 $T = 189185$   $i = 37^{\circ} 35$   
 $e = 0512$   $\lambda = 86^{\circ} 1$   
 $a = 1'' 2212$   $n = -9^{\circ} 0908$ 

### Apparent orbit:

Length of major axis = 2'' 76Length of minor axis = 2'' 38Angle of major axis  $= 142^{\circ}.8$ Angle of periastron  $= 59^{\circ}.5$ Distance of star from centre = 0'' 61

#### COMPARISON OF COMPUTED WITH OBSERVED PLACES

The angular motion during the last three years has not been very rapid, and the constancy of areas shows that the distances have been somewhat undermeasured. It is now apparent that the period will be sensibly longer than Burnham supposed. The value found above is not likely to be in error by more than one year, while the correction of the eccentricity will hardly exceed  $\pm 0.03$ . Considering the small number of observations on which this orbit is based, the elements may be regarded as highly satisfactory. As this system is

194  $\Sigma 2173$ 

visible in the United States, it is worthy of particular attention from American observers.

The following ephemeris gives the place of the companion for five years

t	$\theta_c$	$\rho_c$	$oldsymbol{t}$	$oldsymbol{ heta}_c$	$ ho_c$

tanil, s

196  $\Sigma 2173$ 

When this interesting double star in the constellation Ophruchus was discovered by William Struve, the companion was measured on two nights,\* and again observed in 1831, but in 1836 it had disappeared, so that under the best seeing the star appeared absolutely round Struve therefore suimsed (Mensurae Micrometricae, p 294) that this is a case of occultation similar to those of  $\gamma$  Coronae Borealis and  $\omega$  Leonis, "summa attentione digna". The companion came out on the opposite side in 1840, and was subsequently followed systematically by the best observers, so that at the present time a large amount of good material is available for the investigation of its orbit. The components are so nearly equal in brightness that the angles frequently require a correction of 180°, and for a time it remained uncertain whether the period would be 46 or 23 years. Prof Dunér was the first astronomer who attempted to investigate the orbit of this pair, using measures up to 1876, the illustrious Director of the Observatory of Upsala arrived at the following results:

```
P = 45 	ext{ 43 years} \Omega = 152^{\circ} 65

T = 1872 	ext{ 91} \iota = 80^{\circ} 53

e = 0 	ext{ 1349} \lambda = 7^{\circ} 	ext{ 26}

\alpha = 1'' 	ext{ 009}
```

From an investigation of all the observations, including the measures recently secured at the Leander McCormick Observatory in Virginia, we find the following elements of  $\Sigma 2173$ .

1

```
P = 460 \text{ years} \Omega = 153^{\circ} 7

T = 1869 50 i = 80^{\circ} 75

e = 0 20 \lambda = 322^{\circ} 2

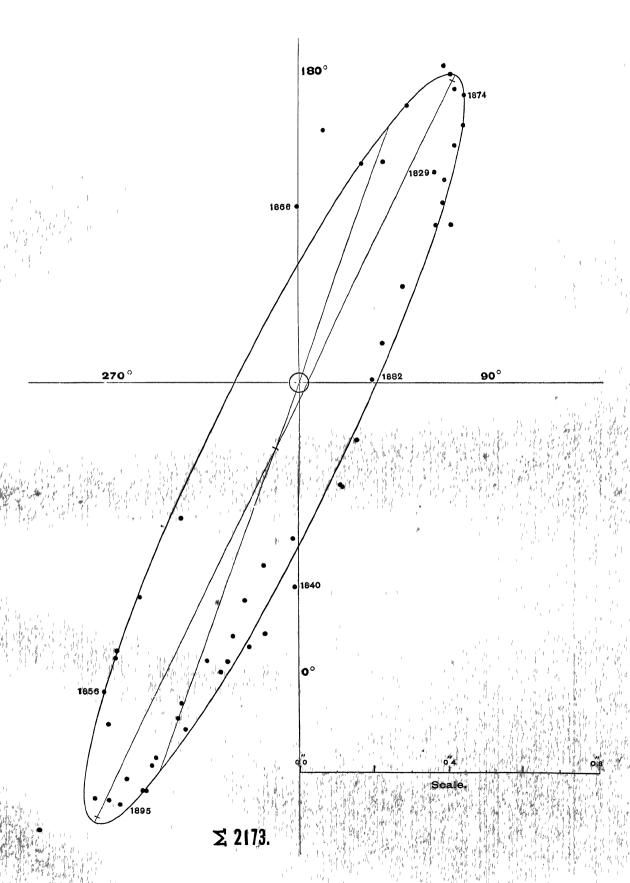

a = 1'' 1428 n = -7^{\circ} 8261
```

### Apparent orbit

Length of major axis = 2'' 22Length of minor axis = 0'' 35Angle of major axis  $= 154^{\circ} 5$ Angle of periastron  $= 160^{\circ} 8$ Distance of star from centre = 0'' 18

The accompanying table of computed and observed places shows that these elements are very satisfactory.

Owing to the high inclination of the orbit, it is clear that a small error in angle would very sensibly alter the apparent radius vector of the companion, and for this reason good measures of distance are more trustworthy than

angles. Therefore, while the present orbit is based on both coordinates, unusual weight has been given to the observed distances

The residuals in angle are very small, except in the case of Englemann's measure of 1885, when the components were so close as to lender all observations with a small telescope very uncertain. It should be remarked that the position for 1882 is based on a measure which was rejected by Schiaparelli on account of its discordance, but as the other six measures by that distinguished astronomer give

$$\theta_o = 109^{\circ} 9$$
  $\rho_o = 0'' 30$ ,

which cannot well be reconciled with the theory of the star's motion, it appears probable that the single outstanding observation is nearer the truth, and it is therefore adopted in the above table.

The most remarkable characteristic of  $\Sigma 2173$  is the relatively small eccentricity of its orbit. Although this element is not so well defined as might be desired, yet the value given above seems to be fairly indicated by the best observations, and is not likely to need any large correction. Good measures of distance about the time of maximum elongation, in 1898 and 1899, would fix the eccentricity more accurately, and accordingly for the next five years this system will deserve the particular attention of astronomers

# $\mu^1$ HERCULIS BC = $\Lambda$ .C. 7.

 $\alpha=17^h~42^m~6$  ,  $\delta=+27^\circ~47^\prime$  94, blush white , 10, blush

Discovered by Alvan Clark in July, 1856

In July, 1856, Alvan Clark discovered that the bluish companion of  $\mu$  Herculis =  $\Sigma$  2220 is a close double star; he estimated the magnitudes of the component to be 10 and 11. The object was first measured by Dawes who predicted the binary character of the system; by repeating his observations in 1859 and 1864, he was able to announce a decided orbital motion. The object has since received considerable attention from the best observers, and the material now available for an orbit is sufficient to define the elements in a very satisfactory manner. Owing to the faintness and difficulty of the pair, the measures must be carefully combined in order to get a satisfactory set of mean places, the distances of some observers are notably too small, and hence they are omitted in forming the yearly means. Most of the early observations of Dawes seem to be affected by sensible errors, and hence we give his work in full.

t	θ.	ρ,	
1857 472	58 97	$1^{''}853$	
$1857\ 562$	60 08	$1.75 \pm$	
1859 650	58 91	$2\ 304$	distance indifferent
1859 691	<b>5</b> 9 <b>5</b> 1	$1\;422$	observation very poor
1859 757	62~02	2 040	difficult in distance
1864 431	77 59	1 806	undoubtedly binary

While measuring the wide pair in 1857, he observed that "the stars B and C certainly point rather to the north of  $\mu$ ." He gives the angle of  $\mu$  Herculis relative to BC as 242°2, and hence we gather that the angle of the pair BC must have been at least 63°.0 Since the allineation of the two faint stars with  $\mu$  Herculis would probably be more exact than even micrometer settings, it seems certain that most of Dawes' measured angles are too small; we have therefore chosen certain nights only in making up the means, and have selected the distances with some regard to the subsequent motion of the star. This selection of Dawes' material is necessary in order to represent satisfactorily the whole series of observations by an orbit based on both angles and distances. The following list gives the elements published by previous computers:

```
P = 45 \text{ 0 years} \Omega = 61^{\circ} 4
T = 1879 \text{ 80} \iota = 64^{\circ} 28
\iota = 0 219 \iota = 180^{\circ} 0
\iota = 1'' 390 \iota = +8^{\circ} 0

Length of major axis
Length of minor axis
Angle of major axis = 2'' 78
= 1'' 148
Angle of periastron = 241^{\circ} 4
```

The period here given can hardly be in error by more than one year, while the uncertainty of the eccentricity probably does not surpass  $\pm 0.02$ . The elements are therefore well defined, and may indeed be regarded as extraordinarily good for an object of such difficulty.

Distance of star from centre = 0" 304

We remark the star is now wider than most observers have indicated by their recent measures. The distance for 1895 is based upon two nights' work, one of the observations being taken by Schiaparelli, the other by the writer at Madison and accidentally omitted in *Astronomical Journal*, No 359. This observation is.

1895 732 43° 2 1" 34 1n See

The images are noted as "good but faint" There is no doubt that the distance is now at least 1".3, and it will increase for some years. Observers should follow this system carefully. The following is an ephemenis

$oldsymbol{t}$	$\theta_c$	$\rho_c$	t	$\theta_c$	ρ <sub>c</sub>

Since the discovery of this double star in 1783, the radius vector of the But while the length of the aic companion has swept over an arc of 285° would ordinarily be sufficient to fix the character of the orbit, it happens unfortunately in this case that the observations are neither very consistent nor very well distributed over the arc; and since by far the greater number of observed positions lie in the sixty degrees described since 1836, a satisfactory determination of the elements is embariassed by difficulties of a somewhat formidable character. But when we examine Hersonel's angle of 1783 in the light of his remarks, there seems to be every reason to regard it as fairly In his notes on the observation of  $\tau$  Ophiuchi, he says. "The closest of all my double stars can only be suspected with 460, but 932 confirms it to be a double star. It is wedge-formed with 460; with 932 one-half of the small star, if not three-quarters, seems to be behind the large star. The morning is so fine that I can hardly doubt the reality; but according to custom, I shall put it down as a phenomenon that may be a deception" If we depend on the approximate accuracy of Herschel's earliest measure, and deduce the areal velocity from the most recent observations, where both angles and distances can be relied upon, we are led to an orbit which will not differ greatly from the truth. The following orbits have been published by previous investigators:

P	<i>T</i>	е.	а	ß	ı	λ	Authority	Source
87 030 120 0 185 2 217 87	1824 8 1820 63	0 03746 0 575 0 5818 0 6055	0 8178  1 111 1 193	55° 5′ 130° 0 69° 31 67° 1	51 47 48 30 53 5 46 8	146 6 28 35	Hind, 1849	AN, 2037

We find the following elements of τ Ophiuchi:

```
P = 230 \text{ 0 years} \Omega = 76^{\circ} 4

T = 1815 \text{ 0} i = 57^{\circ} 6

e = 0592 \lambda = 18^{\circ} 05

a = 1'' 2495 n = +1^{\circ} 5652
```

## Apparent orbit:

Length of major axis = 2'' 46Length of minor axis = 1'' 09Angle of major axis  $= 80^{\circ} 0$ Angle of periastron  $= 85^{\circ} 8$ Distance of star from centre = 0'' 712

The accompanying table shows that this orbit gives a very satisfactory representation of both angles and distances.

The following is an ephemeris for the next five years:

t	$\theta_c$	$ ho_c$	t	$ heta_c$	$\rho_{o}$
1896 50	$25\r{6}$ 7	$1^{''}\!88$	1899 50	$257\overset{\circ}{6}$	1 90
1897 50	257 0	1 89	1900 50	257 9	191
1898 50	257 3	1 90			

It will be evident from what has been said that this orbit is still open to some uncertainty, but a material improvement in the elements will not be possible for many years. Since the companion is at present nearing the apastron of the apparent ellipse, the motion will continue to be very slow; yet the pair will still be worthy of occasional attention from observers. While the period found above is perhaps uncertain to the extent of 15 years, it does not seem probable that the eccentricity can be in error by more than the cordingly there is no probability that even the lapse of ages. The cordingly these elements of  $\tau$  Ophiuchi.

# 70 OPHIUCHI = $\Sigma 2272$ .

Discovered by Sir William Herschel, August 7, 1779.

Researches on the Orbit of 70 Ophiuchi, and on a Periodic Perturbation in the Motion of the System Arising from the Action of an Unseen Body\*

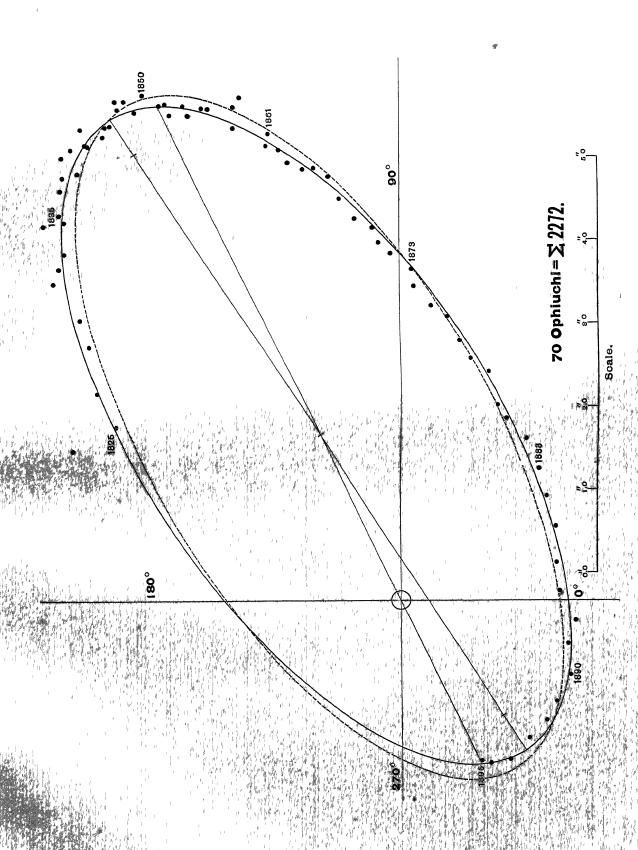

While engaged recently in the observation of double stars at the Leander McCormick Observatory of the University of Virginia, I took occasion to measure 70 Ophiuchi on three good nights (A J. 349). On comparing the results with Schur's ephemeris, four months later, I noticed with surprise that the observed angle was over four degrees in advance of the theoretical place As the Virginia measures had been made under favorable conditions and with extreme care, it became evident that even the orbit to which Professor Schur had devoted so much attention would need revision Accordingly, after all the observations had been collected from original sources and tabulated in chronological order, I proceeded to investigate the orbit in the usual manner, and obtained a set of elements very similar to those which Burnham has given in Astronomy and Astrophysics for June, 1893 On comparing the computed with the observed places there appeared to be a sensible irregularity in the angular motion, and as the observed places were admittedly exact to a very high degree, it was impossible to attribute such large and continued deviations to errors of observation. It was also observed that the sign of  $\theta_o - \theta_c$  showed a peculiar periodicity; the residuals being for many years steadily of one sign, and then as uniformly of the other. After making some unsuccessful efforts to correct the apparent orbit, from which the elements had been derived by the method of KLINKERFUES, I decided to project the orbit found by Schur, so as to compare his apparent ellipse directly with the places given by the mean observations for each year. Though I was aware that Schur's orbit had been based wholly on angles of position, I was not a little surprised to find that the distances had been vitiated in the remarkable periodic manner indicated by the pointed ellipse in the accompanying diagram since I had uniformly adhered to the use of both angles and distances in deriving the orbits of double stars, it was not allowable to violate the distances as Professor Schur had done, nor could we pass over such remarkable periodic errors in the residuals of the angles We were thus confronted with a case in which it was apparently impossible to satisfy both angles and dis-A closer examination of the diagram suggested the idea of a periodic perturbation, alternately in angle and then in distance; and the drawing, in conjunction with the computations, enabled me to see that the case is one worthy of special attention. After some delay (A J. 358) the additional observations

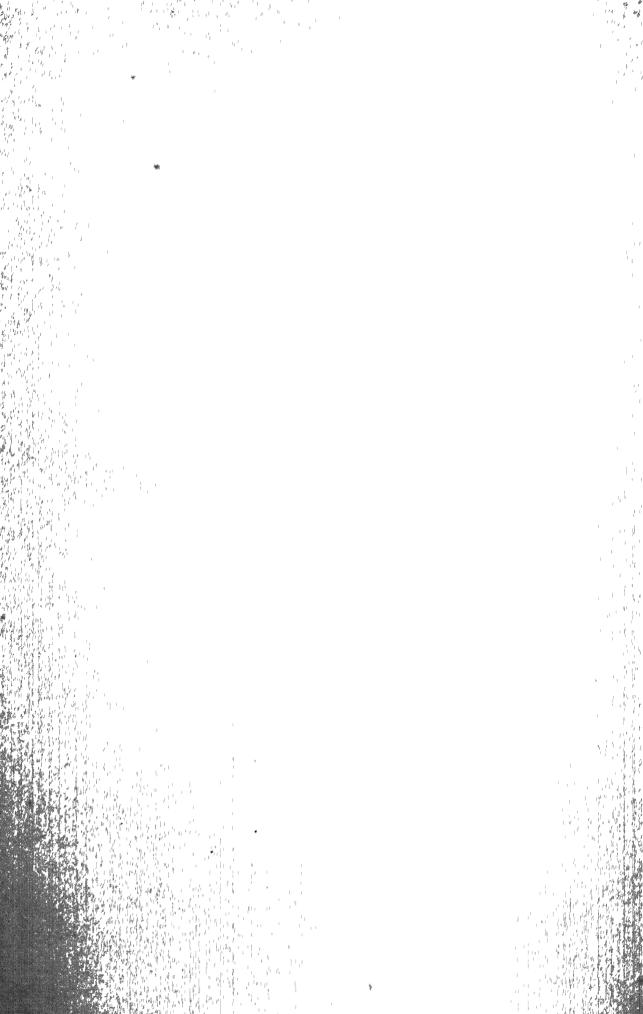

<sup>\*</sup> Astronomical Journal, 363

placed at my disposal by Professors Hough and Comstock, in conjunction with the independent measures made at Madison by Mr. Moulton and myself (A. J. 359) confirmed the correctness of the Virginia measures, and left no doubt of the rapid deviation of the companion from Schur's orbit. Before considering the physical cause of this unexpected phenomenon, I desire to remark that, in the preparation of this paper, my friend Mr. Eric Doulittle, C. E, has rendered valuable assistance. He has carried out the calculations entrusted to him not only with care and accuracy, but also with zeal and enthusiasm, and has, therefore, contributed in no small degree to the early completion of this investigation.

Since SIR WILLIAM HERSCHEL'S discovery of this beautiful system the companion has described considerably more than one revolution. More orbits have been computed for this binary than for any other in the northern sky, but, in spite of the immense labor which astronomers have bestowed upon this star, the motion has proved to be so refractory and so anomalous that the companion has departed from every orbit heretofore obtained. It follows from the phenomena disclosed in this paper that the system contains a dark body, and that no satisfactory orbit can be obtained until this disturbing cause is taken into account. The following list of the orbits found by previous investigators will be of interest to astronomers; in most cases the data have been taken from original sources, but in a few instances we have relied upon the table of elements given by Gore in his useful "Catalogue of Binary Stars for which Orbits have been Computed."

An inspection of this table discloses the fact that the early investigations, so far as they are reliable, led to periods sensibly less than 90 years, while the determinations made between 1845 and 1880, or, when the companion was describing the apastron of the real ellipse, favored a period of at least 94 years. Thus Tisserand and Pritchard, so lately as 1876 and 1878, find periods of 94 93 and 94 44 years, respectively. In 1868 Schur obtained a period of 94 37 years, and similar periods before and since have been deduced by other trustworthy computers.

There is thus unmistakable evidence of a retardation in the motion of the companion near apastron, more recently this inequality has become an acceler-It was observed by Gore in 1888 that the old orbits did not represent recent measures satisfactorily, and, accordingly, he derived a new set of elements with a period of 8784 years, which was substantially confirmed by subsequent work of Mann and Burnham. Finally Professor Schur made an exhaustive investigation of all the observations up to 1893, and adjusted his orbit by the method of least squares to about 400 mean observations of position-angle. He says that in this work he could not advantageously employ the measures of distance, owing to the differences of the individual observers The angles, however, were admitted to be admirably adapted to a fine determination of the elements, and, accordingly, Professor Schur's able discussion of 400 observations inspired the belief that his orbit would give good places of the companion for a great many years, if not for an almost indefinite period. But this just expectation has not been realized, owing to the action of an unseen body which disturbs the elliptical motion of the companion establish the existence and general character of the perturbations thus disclosed we submit the following considerations:

- (1) A reference to Professor Schur's able and exhaustive paper in the Astronomische Nachrichten, No 3220, 21, will enable the reader to judge of the improbability of an orbit based on such a multitude of good measures proving to be defective within two years of its completion, unless disturbing causes were at work to produce the sudden acceleration in angular motion. It is inconceivable that this rapid deviation could take place without a true physical cause. The error in the angle now amounts to about five degrees
- (2) In regard to the older observations we may remark, as Professor Schur and others before him have done, that Sir William Herschel's angles are open to some uncertainty, owing to a possible error in the reading or in the records, so that his observations do not give an exact or trustworthy criterion for the period. Herschel says, however, explicitly, that on "Oct. 7,

1779, the stars were exactly in the parallel, the following star being the largest," and, as it does not seem that any sensible error could affect the angle which he has thus recorded, we see from the measures in 1872-3 that the resulting period would be approximately 92 years. This is an additional indication that the period of this star is not constant. A careful examination of the other early measures shows that the first really good position is that of STRUVE in 1825. These measures are so uniform and consistent, and appear in every way so worthy of entire confidence, that I quote the record from the Mensurae Micrometricae in full.

t	$\theta_{o}$	$ ho_o$		t	$ heta_o$	$ ho_o$

			Mean	1825 56	148 2	3 98	14n Struve

An examination of these separate measures clearly indicates that the error in the mean result does not surpass 0°.5 in angle, and 0″ 1 in distance. By Schur's orbit the angle is corrected two degrees, and when the radius vector is thus thrown forward to 146°.2 the computed and observed distances are nearly identical. As Struve took special pains to secure good measures on a large number of nights, and obtained the foregoing beautiful and consistent results, we may regard his mean position as one of the highest precision. The probable error of such measures would evidently be very small.

(3) We see from the diagram illustrating the apparent ellipse that Schur's orbit falls within the positions given by the measures prior to 1845; so that nearly all the observations of Struve, Bessel, Dawes, Madler, etc., require a sensible negative correction in distance. In figure B the differences  $\rho_o + \rho_o$  of the individual measures used by Schur are plotted to scale, and a glance at the figure will show the improbability of such classic observers as Struve, Bessel and Dawes making the constant errors here indicated. It would be still more remarkable if the observers between 1845 and 1870 have as uniformly erred in the opposite direction. How has it happened that from 1825 to 1845 the distances were steadily over-measured by the best observers, while during the next period the distances were constantly under-measured? Individual observers have what may be called a personal equation (though this far from constant and is difficult to determine with any certainty) but it

could not happen that all the best observers would err alike, although in opposite directions, during the two periods Professor Schur's corrections are evidently inadmissible

- (4) The peculiar periodic manner in which Schur's apparent ellipse crosses and re-crosses the general path which best represents the mean positions, first suggested to my mind the hypothesis of a disturbing body. Figure C is based upon these mean positions, and a comparison with the curve in B shows that the mean positions are typical of all the observations for any given year. Since I was desirous of avoiding any possible prejudice of the material used, I have retained, without alteration, the mean positions which had been formed in August before suspecting the existence of a disturbing influence.
- (5) We suggest that the companion of 70 Ophruchi is attended by a dark satellite, and that the visible companion, therefore, moves in a sinuous curve about the common centre of gravity of the new system, with a period somewhat less than 40 years, and in a retrograde direction As Schur's orbit is based on a least-square adjustment of all the observations extending over two entire revolutions of the invisible body, it may reasonably be inferred that his apparent ellipse will represent very nearly the true motion of the centre of gravity, while the apparent ellipse which best represents the observed distances will give a general outline of the path of the visible star in its sinuous motion. Let us recur to the diagram of the apparent ellipse and imagine that the visible companion and the centre of gravity are in the tangent to the ellipse at the epoch of intersection in 1818 Then, the motion of the visible star being retrograde, we perceive that it will gain steadily on the centre of gravity, and, in 1836, the two will be in line with the original position, after half a sidercal revolution, from 1836 to 1845 the satellite will make another quarter revolution, and again the bright companion will be in the tangent to the apparent ellipse and in advance of the common centre of gravity. As the visible star will now steadily fall behind in its retrograde motion about the centre of gravity, it is clear that from 1845 to 1872, which is three-fourths of a revolution, the motion of the bright body will appear to be abnormally slow This is the apparent retardation previously mentioned as giving rise to the long periods found by computers who used observations extending over the apastron portion of the real orbit. Assuming that the motion is undisturbed, and hence that the areas are constant, Professor Schur was compelled to run his ellipse further out in this part of the orbit in order to represent the observed angles From the diagram we see that the retrograde motion of the visible star continues after 1872, and, as this apparently accelerates the visible

motion of the companion relative to the central star, Schur's ellipse is drawn inside of most of the observations of this period. The falling of the measured distances beyond Schur's orbit shows plainly the periodic motion of the visible star in accordance with the above theory. From this sketch of the effects of the disturbing body it is evident that, at the time Schur completed his orbit, the visible star and the unseen body were nearly in line with the central star. And since the visible companion in 1825, according to Struve, had an angle of 148° 2, whereas Schur makes it 146° 2, or, substantially the same as the centre of gravity at that epoch, it follows that our hypothesis, making Schur's orbit represent the motion of the centre of gravity, is indeed very nearly correct. Any slight correction that may be required for the periastron of Schur's ellipse in order to make it represent the true path of the centre of gravity, had better be deferred until additional observations disclose more clearly the nature and extent of the perturbations.

(6) We may fix the approximate elements of the visible companion about the centre of gravity as follows: From 1818 to 1890, or 72 years, is the time required for two revolutions, as explained in the preceding paragraph, and hence we see that the period is approximately thirty-six years. The motion is retrograde, and from the diagram of the apparent orbit, we may conclude that the distance of the visible star from the common centre of gravity is about 0".3. It is natural to suppose that the plane of the orbit is not greatly inclined to that found by Schur, but existing data will not fix all the elements with the desired precision. Perhaps until the path of the centre of gravity is known with great accuracy, the simple hypothesis of a circular orbit, with node and inclination identical with the similar elements of the visible pair, will be sufficient to explain phenomena, and it follows that both angles and distances are comparatively well represented by this hypothesis.

It is found, however, on more detailed examination that the representation can be somewhat improved by the adoption of the following elements:

P'=36  years	$\Omega' = 151^{\circ}0$
T'=18220	$i' = 60^{\circ} 1$
e'=0475	$\lambda' = 191^{\circ}7$
a' = 0'' 30	$n' = 10^{\circ} 0$

While this orbit gives a good representation of the motion of the bright body about the common centre of gravity, the data are so rough that the determination of such delicate elements must be regarded as provisional only.

In the following table we have compared Schur's elements with the mean

positions for each year; the residuals are given in the columns headed  $\theta_0 - \theta_1$  and  $\rho_0 - \rho_1$ . It is at once evident that the angles are beautifully represented down to 1893, after which the error in angle rapidly accumulates until it now amounts to nearly *five degrees!* The errors in distance are illustrated in diagram C, which shows the same general features as diagram B, where the points represent the individual measures employed by Schur

The elements of the orbit which best represents the observed distances are as follows:

```
P = 88\ 3954\ {
m years} \  Schur's values \Omega = 125^{\circ}\ 7 t = 1808\ 0707 t = 58^{\circ}\ 42 t = 0\ 500 t = 198^{\circ}\ 25 t = 4''\ 548 t = -4^{\circ}\ 0728
```

#### Apparent orbit:

```
Length of major axis = 9'' 00

Length of minor axis = 4'' 17

Angle of major axis = 122^{\circ} 9

Angle of periastron = 295^{\circ} 8

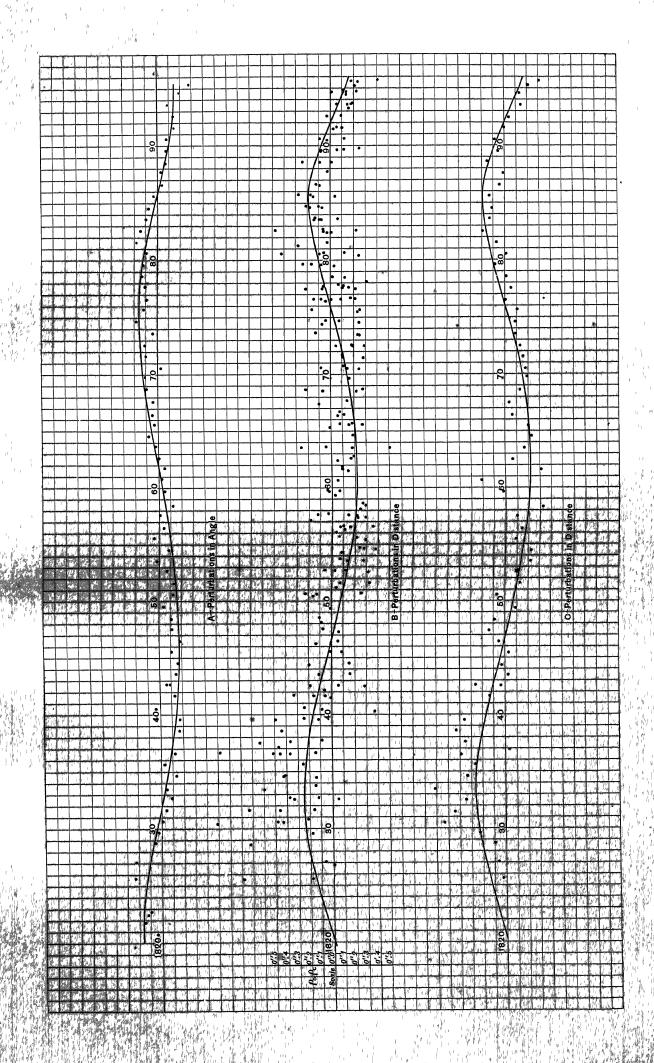

Distance of star from centre = 2'' 198
```

The values of P and T are taken from Schur's orbit, because the values of these elements derived from so many observations may be regarded as very nearly the mean of all the periods and epochs which result from the observa-

tions prior to 1893. The residuals which follow from the use of these elements are given in the columns marked  $\theta_0 - \theta_2$  and  $\rho_0 - \rho_2$ . In the case of the second elements the periodic errors in angle are very noticeable, but, as the simple differences  $\theta_0 - \theta_2$  would not be strictly comparable at different distances, we have reduced all these angular displacements to seconds of the arc of a great circle by the formula

 $\frac{r''(\theta_0 - \theta_2)^{\circ}}{57^{\circ}3} = d\theta''$ 

where r'' denotes the apparent length of the radius vector in seconds of arc, and  $(\theta_0-\theta_2)^\circ$  the residuals of position-angle expressed in degrees The displacement  $d \, \theta''$  is tabulated and also illustrated graphically in diagram Awill be seen that the maximum or minimum displacement in angle is practically identical in time with the zero of the curves of distance in B and C, and that the zero of the curve of angles corresponds to the maximum or minimum of This displacement of phase would be a necessary the curve of distances consequence of the orbital motion of the visible companion about the common centie of gravity, and may be said to establish completely the reality of that The present theory does not require the several phases of the phenomenon curves to be of equal length, since the tangent to the ellipse itself revolves very unequally in different parts of the orbit, and the zero of the curve of distance, for example, depends on the coincidence of this tangent with the line connecting the bright with the dark body

The problem here presented of finding the elements of the orbit of the visible companion from irregularities in the elliptical motion is very much more difficult than those arising from the irregular proper motions of perturbed stars, such as Sirius and Procyon In the case of the phenomena first investigated by Bessel, the centre of gravity of the system moves uniformly on the arc of a great circle, but in this case the centre of gravity moves on the arc of a very small ellipse and with a velocity which follows a very complex law. Indeed the velocity at any point of the oibit is inversely as the perpendicular from the central star to the tangent to the ellipse at the point in question; and, as the central star may in general occupy any point whatever of the apparent ellipse, we see that the velocity varies in an extremely complicated In view of these facts it seems best, especially from the point of view of practical double-star work, to determine first of all the path of the centre of gravity and the elements of its orbit. Suppose we designate the rectangular coordinates of this centre, relative to the principal star, by x', y'; and the coordinates of the visible companion referred to the same origin by

x, y; then if  $\alpha$  and  $\beta$  denote the differences of these coordinates, the observations will furnish a series of equations of the form.

$$\begin{array}{llll} \alpha_1 &= x_1' - x_1 & \beta_1 &= y_1' - y_1 \\ \alpha_2 &= x_2' - x_2 & \beta_2 &= y_2' - y_2 \\ \alpha_3 &= x_3' - x_3 & \beta_8 &= y_3' - y_3 \\ \alpha_4 &= x_4' - x_4 & \beta_4 &= y_4' - y_4 \\ \alpha_5 &= x_5' - x_5 & \beta_5 &= y_5' - y_5 \\ \hline \alpha_n &= x_n' - x_n & \beta_n &= y_n' - y_n \end{array}$$

Five points, each determined by two such equations, are theoretically sufficient to fix the elements of the orbit of the visible star about the common centre of gravity, a larger number of equations, when combined in an advantageous manner, so as to render the errors of observation a minimum, will make the determination more exact, and define the elements with the desired precision. In the case of 70 Ophruchi, Schur's orbit is to all appearances a good first approximation to the path of the centre of gravity, but it does not seem worth while to enter upon the more refined analysis here indicated until additional measures of the visible companion have confirmed the accuracy of this hypothesis. Apart from these theoretical difficulties, the sensible perturbations of the central star upon the motion of its attendant system will give rise to obstacles which are scarcely less formidable.

(9) While we have spoken of the dark body as attending the companion, it is clear that similar phenomena would result from the action of a body revolving round the central star. In this case, however, the considerable distance which would result from a period of 36 years might render the stability of the system somewhat precarious, especially if the orbit be eccentric like that of the visible companion. And as there is every reason to suppose that the system is the outgrowth of nebular condensation, and is, therefore, adjusted to conditions of stability and permanence, it is more natural to regard the companion as the binary. In this case the small mass might give rise to a period of 36 years even if the pair be very close. The separation of the new system is not likely to be less than 0"4, and it may be more than twice that distance. If we adopt the parallax of 0".162 found by Krueger it will follow that the major semi-axis of the orbit of the visible companion is 28.07 astronomical units, and the combined mass is 283 that of the sun; and hence we conclude that the orbit of the visible companion about the common centre of gravity has a major semi-axis of 184 astronomical units. Therefore, while the bright companion describes an eccentric orbit with a major axis which is slightly less than that of Neptune, the action of the dark body causes it to

describe another ellipse, which in size considerably surpasses that of the planet Mars.

- (10) With regard to the position of the dark body we remark that an exact prediction is difficult, but the general indications are that at the epoch 1896 50 it lies approximately in the direction of 260°\*. As the companion is now near periastron, the present is a favorable opportunity for searching for the dark body, since in this position the orbit will be expanded owing to the perturbations of the central star. In case it should be imagined that the unseen body attends the central star, it would be natural to locate it in the direction of 160°.
- (11) Many years ago a disturbing body in the system of 70 Ophruchi was suspected by Madler, Jacob and Sir John Herschel, and on two occasions, more recently, Burnham has searched for it without success. After examining both stars with the Dearborn 18-inch refractor in 1878 he adds: "Both stars round," while a still more critical search with the Lick 36-inch refractor led him to remark "I could not see any third component and both stars appeared to be round, with all powers" In spite of this negative evidence, observers with great telescopes will find this system worthy of special examination. Whatever be the result of optical search for the unseen body, it will now become a matter of great interest to measure the visible companion with the most scrupulous care until the nature and extent of its perturbations are fully established.

#### 99 HERCULIS = A.C. 15.

This difficult double star was discovered by Clark while testing the telescope he had just made for Dawes, at the latter's private observatory.\* The physical connection of the pair was suspected, and during the same year two sets of good measures were obtained by Dawes Otto Struve began to give his attention to the pair the following year, and continued his measures from time to time until 1888. His first observations are very satisfactory, and of the highest value in fixing the elements of the orbit, but the later measures are less trustworthy, owing to the great inequality and closeness of the components. The series of measures begun by Burnham in 1878, and continued until the close of his work in California, is of great importance, and in conjunction with Struve's observations and those recently made by the writer at Madison, enables us to fix the elements with a relatively high degree of precision.

In order to obtain a good orbit from such measures, the means must be formed in a judicious manner, regard being had to the known motion of the companion. After careful study of all the observations, we have formed a suitable set of mean places, and deduced the corresponding elements. The orbits previously found for this system are:

While this orbit may need slight modification in the course of time, it does not seem probable that a sensible improvement can be effected for a good many years, as the motion is now very slow, and chiefly in the direction of the radius vector. The orbit is remarkable for its high eccentricity, and for having no sensible inclination. This circumstance enables us to contemplate directly the real orbit, and renders 99 Herculis an object of the highest interest. The pair is always rather difficult, owing to the inequality of the components, and exact measurement is seldom possible. But at present the star is relatively easy, and ought to be given some attention by observers.

Owing to the great southern declination of  $\zeta$  Sagittarii, which renders it maccessible to European observers, and makes observations difficult even in the United States, the object was comparatively neglected for a number of years. The first observations were made by Winlock and Newcomb in the year of its discovery. The pair was not again observed until 1878, when Burnham began to give it regular attention. His series of measures now show that  $\zeta$  Sagittarii belongs to the class of bright, close binaries with short periods. This object has therefore become one of particular interest to American observers.

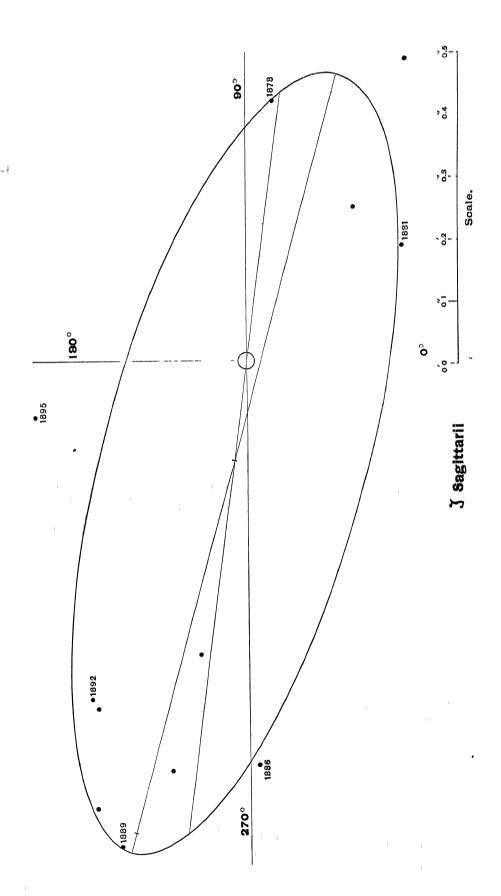

The first investigation of the orbit was made by Mr J E Gore, who published the following elements (Monthly Notices, RAS, 1886, p 444)

$$P = 1869 \text{ years}$$
  $i = 58^{\circ} 8$   
 $T = 188286$   $\Omega = 83^{\circ} 37$   
 $e = 01698$   $\lambda = 263^{\circ} 35$   
 $\alpha = 0'' 53$ 

MR J W Froley has more recently examined this orbit (Astronomy and Astrophysics, June, 1893), and obtained a set of elements which do not require any large corrections:

$$P = 17715 \text{ years}$$
  $\Omega = 75^{\circ}35$   
 $T = 187862$   $\iota = 73^{\circ}95$   
 $\ell = 030$   $\lambda = 327^{\circ}35$   
 $\ell = 0000$ 

<sup>\*</sup> Astronomical Journal, 355

While in Virginia recently, I took occasion to measure this star, and, although the object was seen with difficulty, owing to its low altitude, I could discover a distinct elongation in the direction 194°7, the distance could not be fixed with much confidence, but my settings of the micrometer gave 0"35. The estimates of distance were substantially the same, but I am now convinced, from my distinct recollection of the appearance of the object, that both the measure and the estimate were too large. The star could not be separated, although it was sharply elongated with a power of 1300, the distance was probably less than 0"25

From an examination of all the measures of this pair, we have derived the following elements.

$$P = 18.85 \text{ years}$$
  $\Omega = 69^{\circ} 3$   
 $T = 1878.80$   $\iota = 67^{\circ} 32$   
 $\iota = 0.279$   $\lambda = 328^{\circ} 1$   
 $\iota = 0.07686$   $\iota = -19^{\circ} 0.098$

#### EPHEMERIS t $\rho_c$ $\theta c$ $\rho_c$ 0.37 498 0 24 1899 50 118 1 1896 50 0 47 1900 50 299 028 1897 50 76563 5 0 46 1898 50

When we consider the small number of observations, and the discordant character of some of them, we must regard these elements as highly

satisfactory. It is not likely that they will be materially changed by future observations, but for some time this rapid binary will deserve careful attention. The eccentricity of the orbit appears to be fairly well defined, and is rather smaller than usual; good observations during the next five years will enable us to fix this element with the desired precision. The star is now very difficult, and will remain so for several years, but it is constantly within reach of our large refractors

During his sojourn at Feldhausen Herschel made careful measures of this object with the seven-feet equatorial, and on two occasions swept over it with the twenty-feet reflector \* In sweep 461 he saw the pair under specially favorable conditions, and estimated the distance of the components at 3". This value is therefore adopted in the table of observations instead of the distance (1"23") indicated by the micrometer, which was viriated by troublesome hitching of the threads, and had to be rejected as worthless. Herschel showed from his observations that the system had a considerable retrograde motion, and hence it was subsequently followed by Jacob, Powell, Russell, Tebbutt and other southern observers. At the present time the are described amounts to 238°, and even if the observations are not very numerous, they are sufficient, both in point of quantity and quality, to give an orbit which will undoubtedly prove to be substantially correct

The components are nearly equal in magnitude, and, as they are never closer than 1"42, the pair is always comparatively easy, and even if difficulties arise in the measurement of distance, there will be practically no difficulty, as Herschiel remarks, in determining the angle with the necessary accuracy. In dealing with the orbit of a bright pair with equal components, it is clear that unusual weight should be given to the position angles, and especially when the stars are fairly wide, but the measured distances are affected by relatively large errors. The orbit of this star is therefore based mainly on the angles, but the distances have been of no small service in the final definition of the elements. Some of the orbits which have been published by previous investigators are as follows.

It will be seen that my orbit is quite similar to that found by Gore. Though the period is not defined with the greatest accuracy, it does not seem probable that the value given above can be uncertain by more than five years. The eccentricity will certainly be in the immediate neighborhood of the value here assigned, and an error exceeding  $\pm 0.02$  is very improbable. The orbit of  $\gamma$  Coronae Australis is therefore comparatively well determined, and yet as great accuracy in the orbits of double stars is ultimately desirable, southern observers will find this system worthy of constant attention.

When discovered in 1873 the companion was near its maximum elongation, and was easily measured by Dembowski in 1874. The measures of the next few years showed that the pair had a rapid direct motion \* In 1879-80 the distance of the components became so small (about 0" 20) that the object could be elongated only by the most powerful telescopes. The measures at this time are therefore few in number, and necessarily of doubtful accuracy.

Since the epoch of Dembowski's measures in 1874, the radius-vector of the companion has swept over 335 degrees of position-angle, and the intervening observations enable us to determine the orbit with a comparatively high degree of precision. The following table gives the orbits hitherto published for this star

P	T	e	а	Ω	ı	λ	Authorn	ty	Source

From an investigation of all the observations we find the following elements for  $\beta \ Delphini$ .

$$P = 27.66 \text{ years}$$
  $\Omega = 3^{\circ} 9$   
 $T = 1883.05$   $\iota = 61^{\circ} 35$   
 $e = 0.373$   $\lambda = 164^{\circ} 93$   
 $\alpha = 0'' 6724$   $n = +13^{\circ} 015$ 

### Apparent orbit:

Length of major axis = 1'' 060Length of minor axis = 0'' 477Angle of major axis  $= 2^{\circ} 5$ Angle of periastron  $= 176^{\circ} 6$ Distance of star from centre = 0'' 194

<sup>\*</sup> Astronomical Journal, 857.

	•		

The accompanying table of computed and observed places shows that these elements are extremely satisfactory. The only large residual is that of 1880, which is probably due to an error of observation incident to the excessive closeness of the components

The present orbit is somewhat more eccentric than those heretofore published, and in this respect it conforms better to the general rule among binaries. That the orbit has an eccentricity of about this magnitude is evident from the rapid motion of the radius-vector in the periastral region, and its slow motion at the present time. The slow, angular motion of the radius-vector during recent years indicates, of course, that the distance of the companion is much increased, and this leads us to remind observers that the present distance is sensibly larger than some have indicated by their measures. At present the distance is probably over 0" 65, and for some years will slightly augment

It does not seem at all probable that the true elements of this remarkable binary can differ materially from those here obtained. Nevertheless, additional exact measures will be valuable in fixing the orbit with great accuracy, and as the star will be relatively easy for several years, observers should give it regular attention. The following is a short ephemeris:

t	$\theta_c$	ρε	$oldsymbol{t}$	$\theta_c$	$\rho_c$
- 000 H-	2220	0,774	4000 84	٥	"

This double star is always an exceedingly close and difficult object WILLIAM HERSCHEL measured the position-angle in 1783, and on repeating his observation in 1802, concluded that in nineteen years the motion had amounted to 37° 4 (Phil Trans, 1804, p 371) In 1825 the star was measured by Struve on two nights, his observations gave  $\theta = 25^{\circ} 0$ ,  $\rho = 0'' 81$ ,  $\theta = 30^{\circ} 0$ ,  $\rho = 0'' 80$ These results do not accord well with those of 1802, but we may infer with-DAWES (Mem RAS., vol xxxv p 427) that Herschiel's second observation is For it is clear that the angle could not have been the same in 1802 as in 1825, and the subsequent motion of the star shows that Struve's first position is essentially correct. All the early and some of the more recent measures of 4 Aquarii are extremely discordant, and great difficulty is experienced Careful sifting of the in determining what measures ought to be relied upon observations and judicious combinations of individual results will alone insure suitable mean places for the derivation of a satisfactory set of elements have relied principally upon the work of SIR WILLIAM HERSCHEL, STRUVE, SIR John Herschel, Dawes, Madler, Secchi, Dembowski, Hall, Burnham, Schiaparelli and Comstock

The following elements of 4 Aquarii have been published by previous computers

P	T	e	а	Ω	ı	λ	Authority	Source
129 8 126 65		0 46 0 543				$235^{\circ}0 \\ 74^{\circ}25$	Doberck, 1877 See, 1895	

A revision of my former orbit of this star gives the following elements

$$P = 129 \text{ 0 years}$$
  $\Omega = 177^{\circ} \text{ 7}$   
 $T = 1899 \text{ 40}$   $i = 72^{\circ} 53$   
 $e = 0.514$   $\lambda = 68^{\circ} 63$   
 $a = 0'' 732$   $n = +2^{\circ} 7907$ 

#### Apparent orbit

Length of major axis = 1'' 288Length of minor axis = 0'' 43Angle of major axis  $= 0^{\circ} 3$ Angle of periastron  $= 215^{\circ} 2$ Distance of star from centre = 0'' 173

The accompanying table of computed and observed places shows a very satisfactory agreement. The present orbit is narrower than the one recently published in the *Astronomical Journal*, 341, but the great discordance of results of individual observers shows that the object has always been extremely close;

and hence we think the chances favor the present orbit, which differs from the previous one chiefly in the higher inclination. It is noticeable that the representation of the more recent observations is sensibly improved.

The period here indicated is not likely to be in error by more than five years, while a variation of  $\pm 0.03$  in the eccentricity does not seem probable. It is therefore unlikely that future observations will greatly alter the present elements, but as some improvement is still desirable, astronomers should continue to give this star careful attention. During the next few years the motion will be very rapid, and the object excessively difficult, but for this very reason observations will be the more valuable

The following is an ephemeris for five years:

$oldsymbol{t}$	$oldsymbol{ heta}_{\epsilon}$	$ ho_c$	$oldsymbol{t}$	$oldsymbol{ heta_c}$	$\rho_c$

The pair was first measured in 1852, and when the observations were repeated the following year it was found that there was a slight diminution in the angle of position as well as in the distance. In 1854 and in 1856 the star was noted as single, but in 1857 the companion appeared in the opposite quadrant, and hence it became evident that the star is a binary in rapid retrograde motion. Continued observation disclosed the fact that the orbit is highly

inclined upon the visual ray, and STRUVE's measures seemed to indicate a period of 65 or 13 years. Since 1877 the star has been carefully followed by BURN-HAM, and by means of his fine series of observations we are enabled to derive a very satisfactory orbit.

The two orbits heretofore published for this star are as follows

P	T	e	а	ಬ	ı	λ	Authority	Source
11 48 11 45	1892 0 1892 80	0 20 0 14	$\begin{bmatrix} 0.41\\0.452 \end{bmatrix}$	$2\overset{\circ}{4}0$ $22\ 2$	81 <sup>°</sup> 8 79 05		Wrublewsky, 1887 See, 1895	AN, 2771 AN, 3290

An investigation of all the observations leads to the following elements of  $\delta$  Equiler

$$P = 1145 \text{ years}$$
  $\Omega = 22^{\circ} 2$   
 $T = 189280$   $\iota = 79^{\circ} 0$   
 $\iota = 0165$   $\lambda = 0^{\circ} 0$   
 $\iota = -31^{\circ}.441$ 

Apparent orbit

Length of major axis = 0'' 904Length of minor axis = 0'' 171Angle of major axis  $= 22^{\circ} 2$ Angle of periastron  $= 22^{\circ} 2$ Distance of star from centre = 0'' 075

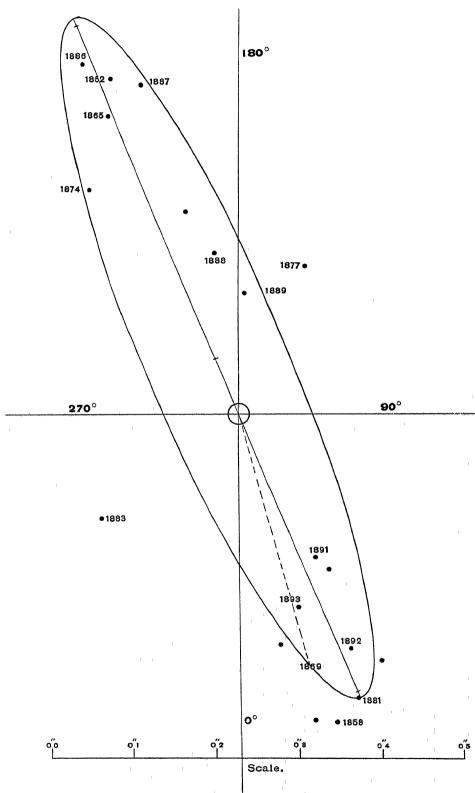

The following table gives a comparison of the computed with the observed places, and shows that the present elements will never require any considerable correction. Only a few large deviations occur, and these are probably to be explained by the extreme difficulty of the object \*

BURNHAM's measure of 1877 is marked "doubtful," and is practically only an estimate, as the object was very difficult to separate

It will be seen that the eccentricity of this orbit is considerably smaller than that generally found among double stars. It is also remarkable that the real major axis coincides with the line of nodes, so that  $\lambda$  is zero

 $\delta$  Equuler and  $\kappa$  Pegasi are the most rapid binaries in the heavens, and on this account are worthy of special attention from observers who have large telescopes. The elements given here need to be tested by further observation. It is especially important to determine the maximum distances of the companion when the angles are about 22° and 202° respectively, as this would furnish a more exact determination of the eccentricity and the major axis.

This remarkable double star was discovered with the 18-inch refractor of the Dearborn Observatory. Its extreme closeness led to the belief that it would prove to be binary,\* and accordingly it has been found to be in rapid revolution. Dr Englemann of Leipzig succeeded in making one measure of the pair in 1883, which indicated a retrograde motion. Burnium's measures were continued at the Lick Observatory from 1888 to 1892, and the new data thus obtained enabled him for the first time to get the approximate period of revolution (Monthly Notices, March, 1891)

At the request of Burnham and the writer, Barnard has since followed the star, and obtained additional measures which appear to be sufficient to give us a reasonably good approximation to the elements of the orbit. In his first examination of the motion of this pair, Burnham made the orbit nearly circular, but the recent observations show that the orbit has about the usual eccentricity prevailing among binaries, and that the inclination of the orbit is very high. In the Monthly Notices for November, 1891, Mr. Lewis has given a set of measures recently obtained with the Greenwich 28-inch refractor, and sketched an apparent orbit which would better satisfy the latest observations.

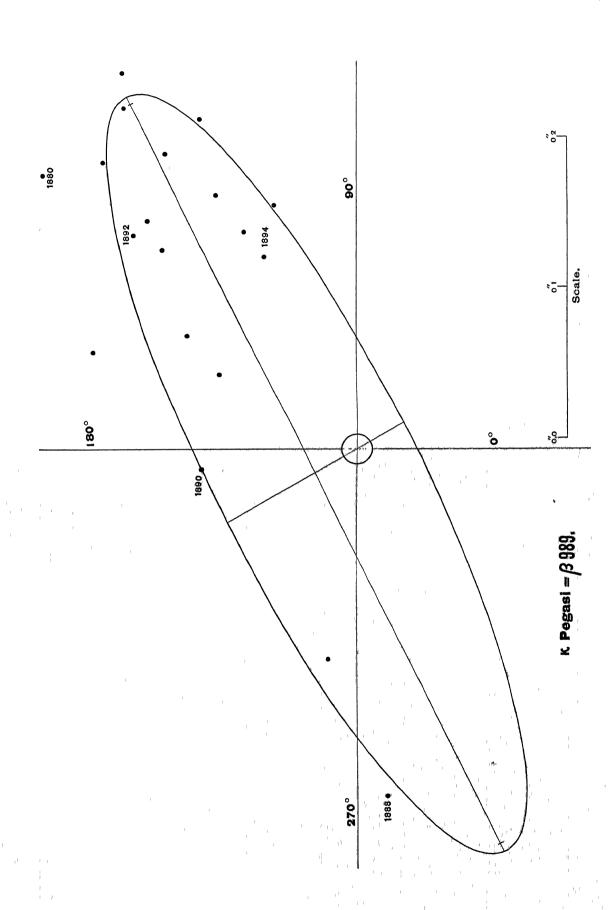

Having collected all the observations of this difficult star, including some unpublished measures kindly furnished by Barnard last Autumn, we have investigated the orbit by the method of Klinkerfues, and find the following elements:

$$P = 11 42 \text{ years}$$
  $i = 81^{\circ} 2$   
 $T = 1896 03$   $\Omega = 116^{\circ} 25$   
 $e = 0 49$   $\lambda = 89^{\circ} 2$   
 $a = 0'' 4216$   $n = -31^{\circ} 5236$ 

### Apparent orbit:

The agreement must be considered very satisfactory when account is taken of the extreme closeness of the components, and the high inclination of the orbit, which permits a small error in angle to have a marked effect on the distance. From an examination of all the measures it seems probable that most observers have underestimated the distances, and this certainly must have been the case with Dr Englemann, who used only a 7.5-inch refractor, and therefore could not have divided the components at a distance of 0"16. The computed distance is therefore much more probable, and especially since the elements are based principally upon the excellent measures of Burnham and Barnard, made with the 36-inch refractor of the Lick Observatory.

BURNHAM has repeatedly called the attention of astronomers to the high importance of systematically following such extremely rapid binaries with large telescopes, so that we could in a few years derive orbits, which, in the case of most stars, would require the observations of centuries.

We would beg to add that it is not only important to observe  $\kappa Pegasi$  annually, but especially at certain critical parts of its orbit, where measures would enable us to fix the eccentricity and the inclination more accurately. Thus, according to the above elements, the minimum distance will occur just

after periastron passage in 1896 03, and measures made on either side of the periastron will be very valuable. At the minimum distance (0".034) the star will be single in the largest telescope in the world, but it would be important to ascertain just when this disappearance takes place, and how long it lasts According to the above orbit, the companion ought to be visible in a 30-inch refractor until August, 1895, and hence we suggest that observers should watch for it during the Summer of 1895 and the Autumn of 1896. Good observations at these epochs will be of the greatest value in improving the elements of the orbit.

 $85 \text{ PEGASI} = \beta 733.$

Since Burnham's discovery of this rapid binary, the companion has described an arc of 285°\* The components are of the 6th and 11th magnitude and so great an inequality in brightness combined with the closeness of the pair, renders exact measurement very difficult. Therefore it is not strange that

<sup>\*</sup> Astronomische Nachrichten, 3339

the position-angles as well as the distances obtained by the same or by different observers should occasionally exhibit sensible discrepancies. Yet when the measures are properly combined into suitable yearly means we obtain a series of places which will give an orbit that is substantially correct

The first orbit of this pair was computed by Professor Schaeberle in 1889; his elements are

P = 223 years	$\Omega = 306^{\circ} 1$
T = 1884~00	$i = 68^{\circ} 6$
e = 0.35	$\lambda = 70^{\circ} 3$
a = 0'' 96	$n = +16^{\circ} 144$

This orbit represents the measures prior to 1891 with the desired accuracy, but the error in angle rapidly accumulated and in 1892 surpassed 20°. Accordingly, Professor Glasenapp attempted an improvement of the orbit (AN 3145), and obtained a set of elements which rendered the residuals in angle exceedingly small.

$$P = 17 487 \text{ years}$$
  $\Omega = 307^{\circ} 32$   
 $T = 1884 21$   $i = 66^{\circ} 74$   
 $e = 0 164$   $\lambda = 69^{\circ} 73$   
 $u = 0'' 80$   $n = +20^{\circ} 586$ 

Nevertheless the ephemeris computed by Professor Glasenapp has signally failed of its purpose, as the error now amounts to about 80°. As the investigation was based wholly on angles of position we may infer that these coördinates were affected by sensible systematic errors, which might the more easily result from the inequality of the stars.

The careful measures which I recently secured at the Washburn Observatory (A.J. 359) have enabled me to make a new determination of the orbit based on all the material of a trustworthy character. We find the following elements of 85 Pegas:

$$P = 24 \text{ 0 years}$$
 $\Omega = 116^{\circ}.3$ 
 $T = 1883 80$ 
 $\iota = 55^{\circ} 6$ 
 $e = 0.388$ 
 $\lambda = 265^{\circ} 4$ 
 $\alpha = 0'' 8904$ 
 $n = +15^{\circ} 0$

We are justified in predicting that the true period of 85 Pegasi will not differ from the value given above by more than one year, and that the error of the eccentricity will not surpass  $\pm 0.02$ . The good representation of the angles and distances shows that the other elements are equally satisfactory. The foregoing elements will therefore never be greatly changed, but some improvement is desirable, and observers with great telescopes should continue to give this important system regular attention. The following is an ephemeris for the next five years

## CHAPTER III.

RESULTS OF RESEARCHES ON THE ORBITS OF FORTY BINARY STARS, WITH GENERAL CONSIDERATIONS RESPECTING THE STELLAR SYSTEMS

## § 1 Elements of the Orbits of Forty Binary Stars.

In the preceding chapter we have presented detailed researches on the orbits of forty stars. To enable the reader to grasp readily the existing state of our knowledge, we have also included diagrams of the apparent ellipses, and of the mean observations from which the elements were derived. In many cases we have seen that the observations are relatively rough, and that while the errors are small absolutely, they are yet very large in comparison with the minute quantities measured. Under these circumstances it seemed useless to attempt a Least Square adjustment of the residuals, and hence we have through-cessive approximations of an empirical character. Accordingly, the orbits are not definitive, but for reasons indicated in the several cases the changes which future observations may necessitate will be confined within narrow limits.

In the following Table we give a summary of the elements, with the probable uncertainty still attaching to the period and the eccentricity. From the variations of these elements it is easy to see about the extent of the alterations which may be required in the adopted values of the other elements. The final changes which future observations may produce in any given orbit can not yet be determined with certainty, and hence our variations may occasionally turn out somewhat too small; but as care has been exercised to avoid overestimation of the accuracy of results, the values here indicated ought not to prove very deceptive.

In glancing over the apparent orbits of the preceding chapter the reader should remember that the adopted elements depend not only on the agreement of the observed distances with the apparent ellipses, but also on the accuracy with which the law of areas is satisfied. These two criteria seem to justify the comparatively small variations indicated in the Table of elements; but as

the orbits here presented depend essentially on the observations employed, and as our choice is to some extent a matter of judgement, it is not certain that we have always arrived at the best results

(\*) Angle I'er = 169° 5

In the course of the next twenty years a sensible improvement can be effected in the orbits of rapidly moving stars, such as  $\kappa$  Pegasi, but mean-

while the elements here adopted will give ephemerides sufficiently exact for the use of observers

Vigorous prosecution of the measurement of double stars will furnish the

material for one hundred orbits at the end of another half century, and accordingly such effort is urgently demanded by the highest interests of science.

### § 2 Relative Velocity of the Companion in the Line of Sight for the Epoch 1896 50

When the elements of the orbit are known, the theory developed in §5, Chapter I, first published in the Astronomische Nachrichten, No 3314, enables us to predict the relative motion of the companion of a binary in the line of sight for any given time. The columns marked  $\frac{\rho}{a}$  and  $\pm \frac{\kappa}{a}$  in the foregoing Table contain the desired results for the epoch 1896 50 The numbers in the column  $\frac{\rho}{\alpha}$  express the orbital velocities in units of the radius of the hodograph As the scale of this radius is unknown, except in a very few cases, we are not able to express this velocity in kilometres or in other absolute units, but when the parallaxes are determined this may be readily accomplished column as it stands, however, shows the rate of orbital motion, compared to what is approximately the average velocity, and we are thus enabled to select those stars which have a rapid orbital motion. If the motion of any given pair be rapid, and also mainly in the line of sight, as in the case of 70 Ophiuchi, the system so circumstanced will be favorable for spectroscopic The column  $\pm \frac{\kappa}{2}$  shows what part of the orbital motion is in the measui ement line of sight, and this enables us to select for measurement with the Spectrograph those pairs which have a large orbital velocity with the major portion of it towards or from the earth

The stars at present the most favorably situated for measurement of the relative motion in the line of vision are  $\eta$  Cassiopeae, a Canis Majoris, 9 Argûs,  $\xi$  Bootis,  $\gamma$  Coronae Borealis,  $\Sigma 2173$ , 70 Ophruchi,  $\beta$  Delphini, and a Centauri

Adopting parallaxes of 0" 75, 0" 162, and 0" 154 for a Centaur, 70 Ophruch, and  $\eta$  Cassiopeae respectively, we find the line-of-sight components for the several systems to be 6.66, 13 95, 8 89, where the unit is the kilometre. These quantities are well within the limit of spectroscopic measurement, and therefore an experimental determination offers an attractive problem to observers occupied with this branch of Astronomy

It will be seen that several of the above stars are wide, while others are very close. If the two spectra can be photographed on the same plate, the lines being only slightly displaced by the relative motion of the stars, as in the case of spectroscopic binaries, the close pairs ought to be as easily measured as the wide ones, whose spectra could perhaps be photographed separately

In any case the prosecution of these researches with the powerful spectroscopic appliances of the great telescopes of our time is an urgent desideratum

of Astronomy. And until the relative motions of visible systems are thus determined there will remain some doubt as to the reality of the so-called spectroscopic binaries, not that any one doubts the theoretical validity of the Doppler-Huggins principle, but rather that other explanations of the phenomena interpreted as spectroscopic binaries are considered possible. Moreover, the great interest attaching to investigations which will give the absolute dimensions, parallaxes and masses of binary systems, as well as the possibility of testing the validity of the law of gravitation, ought to induce astronomers to prosecute these studies with a zeal commensurate with their real importance

Owing to the small size of the earth's orbit, it seems that our principal hope for knowledge of the dimensions of the universe must be based upon this method. The change in wave-length due to motion in the line of sight was originally pointed out by Döppler, but Huggins was the first to apply the Spectroscope to the heavenly bodies, and to reduce Döppler's principle to actual practice, and to assign it a place in modern Astronomy. The application of the principle to the determination of the dimensions of binary systems was first proposed by Fox Talbot. But as his theory was restricted to the case of circular motion, it could not be applied to the eccentric orbits described by the stars, and accordingly it has since been somewhat varied and extended by others. The theory which we have developed is entirely general for ellipses of every possible eccentricity, and from the point of view of rigor and generality leaves nothing to be desired.

# §3 Investigation of a Possible Relation of the Orbit-Planes of Binary Systems to the Plane of the Milky Way

Owing to the well known arrangement of the stars and sharply-defined nebulae with respect to the Milky Way, it has been suggested that some relation might exist between the planes of the stellar orbits and this fundamental plane of the universe. An examination of this question is worthy of the attention of astronomers, and accordingly we shall compute the inclinations of the foregoing orbits by the formulae developed in the Berliner Astronomisches Jahrbuch for 1832. The method of transformation which Encke has employed enables us to refer the plane of a double-star orbit to any absolute plane in space.

Let us pass a plane through the central star parallel to the equator. The pole of this plane will meet the celestial sphere at the same point as the pole

of the heavens Consider the triangle connecting the pole of the equator with the poles of the real and of the apparent orbit. The pole of the apparent orbit is determined by the right ascension and declination of the star  $(a, \delta)$ . Let the coordinates of the pole of the real orbit referred to the same axes be A and D, and let  $\Omega'$  be the angle which the great circle passing through the poles of the real and apparent orbits makes with the meridian. The arc joining the poles of the orbits is the inclination, i, and this is one of the elements given in the foregoing Table. From the resulting spherical triangle we have

$$\sin D = \cos \iota \sin \delta + \sin \iota \cos \delta \cos \Omega' = m \cos (M - \delta),$$

$$\cos D \sin (\alpha - A) = \sin \iota \sin \Omega',$$

$$\cos D \cos (\alpha - A) = \cos \iota \cos \delta - \sin \iota \sin \delta \cos \Omega' = m \sin (M - \delta),$$
where
$$\sin \iota \cos \Omega' = m \cos M,$$
and
$$\cos \iota = m \sin M$$
Then
$$\tan M = \frac{1}{\tan \iota \cos \Omega'},$$

$$\tan (\alpha - A) = \frac{\sin (M - \delta)}{\cos M \tan \Omega'},$$

$$\tan D = \frac{\cos (\alpha - A)}{\tan (M - \delta)}$$

When the light ascension and declination of the pole of the real orbit have been determined, we may pass a plane through the central star parallel to the Milky Way. In the spherical triangle which joins the pole of this plane with the pole of the real orbit and the pole of the heavens, the inclination of the real orbit to the plane of the Milky Way is given by the arc connecting their poles. Thus we have

$$\cos \Gamma = \sin D \sin \delta' + \cos D \cos \delta' \cos (A - \alpha'),$$

where a' and 8' denote the coordinates of the north pole of the Milky Way

In our computations the coordinates of the north pole of the Milky Way are taken on the authority of Sir John Herschel, who found

$$\alpha' = 12^{h} 47^{m}$$
 ,  $\delta' = +27^{\circ}$ 

There are two solutions for  $\Gamma$ , owing to the two values of  $\Lambda$  and D incident to the indetermination of the ascending node, and the resulting inclinations to the Galaxy are tabulated as  $\Gamma$  and  $\Gamma'$ . Now, we do not know which of these two possible inclinations to the Milky Way is correct, but since it is impossible to select from either column any one prevailing angle, much less an evanescent inclination, we conclude that the orbits are not directly related to the Milky Way, or to any other fundamental plane of the heavens. Thus it is clear that the orbit-planes lie at all possible angles to the Milky Way, with no

marked relation to the general scheme which distinguishes the arrangement of the stars and well-defined nebulae. The consideration that the size of a stellar orbit is small compared to the dimensions of the Milky Way, and that the number of such systems is very great, might have enabled us to anticipate this result as probable à priori, since the condensation of nebulous matter to so many centres would almost of necessity have produced rotations in all possible planes, and even if confined originally to one plane the parallelism would have been disturbed by the action of foreign bodies during the ages required for the development of the visible universe.

### §4. High Eccentricities a Fundamental Law of Nature.

如事和

It thus appears that the inclinations of the orbit-planes bear no definite relation to any given plane of the heavens, and an examination of the periods of revolution shows that this element likewise has no characteristic property. The periods are found to range from 11 to 370 years.

It is evident that such elements as T, a,  $\alpha$ ,  $\alpha$ ,  $\lambda$ , can have no relation to physical causes, and an inspection of the Table shows no trace of such a connection. When, however, we came to deal with the eccentricity the case is different. The results given in the preceding Table establish a most remarkable law, which is of fundamental importance in our theory of the origin and development of the stellar systems, and is besides of practical value to working astronomers

On glancing over the eccentricities it is found that while nearly all values exist, few, if any, are very small like those of the planets and satellites, nor are any very large like those of the long-period comets. The smallest eccentricity is that of  $\xi$  Scorpii, e = 0.131, the largest that of  $\gamma$  Virginis, e = 0.897, the mean value for the forty orbits, e = 0.482

Let us take the x-axis as the axis of eccentricity, and the y-axis as the axis of number of orbits, and divide the interval from e = 0.0 to e = 1.0 into a convenient number of parts. Then, if we erect ordinates denoting the number of orbits falling in the given intervals, and connect the points thus determined, we shall be able to illustrate the distribution of orbits as regards the region of eccentricity.

We find no orbits between 00 and 0.1; two between 0.1 and 02; four between 02 and 03, eight between 0.3 and 0.4; nine between 0.4 and 0.5; nine between 0.5 and 0.6, two between 0.6 and 0.7, four between 0.7 and 0.8,

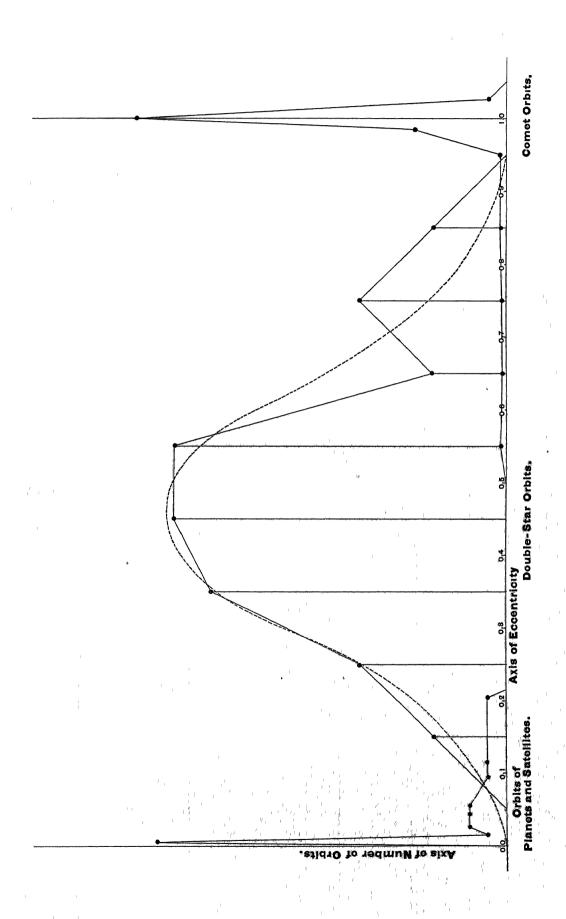

two between 0.8 and 0.9; none between 0.9 and 1.0. The distribution is illustrated by the broken line in the accompanying figure. Since the number of orbits is finite, the figure is an irregular line, if the number were indefinitely increased, the figure ought to become approximately a smooth curve

It is evident, therefore, that the time curve of distribution of orbits resembles a probability curve with maximum near 0 482, the slope in either direction is gradual, but the curve vanishes before it reaches zero and unity. We have drawn a pointed curve to illustrate what is conceived to be the probability curve for the distribution of orbits, but it is based on forty orbits only, and therefore is necessarily provisional. We may observe, however, that forty is a number sufficiently large to realize the essential conditions underlying the theory of probability, and accordingly we are justified in the inference that the nature of the curve here indicated will never be greatly changed. There is an irregularity in the broken line between 0.6 and 0.7, which may be attributed to the effect of chance, if the number of orbits were greatly increased this gap would be filled up. In general, there will be irregularities in the distribution so long as the number of orbits is finite, but they ought to become less marked as the number is increased.

Thus, it is clear that in whatever intervals the axis of eccentricity be divided, and however the number of orbits be increased, there will remain in the curve of distribution a conspicuous maximum near 0.482, with a gradual slope in both directions. The following table shows the eccentricities of the orbits of the planets and satellites (*Inaugural Dissertation*, Berlin, 1893, p. 58):

Planet	Eccentricity	Mean Eccentricity	Planet	Eccentricity
Venus	0 00684	0 06026	Jupiter	0 04825

The orbits of several satellites appear to be circular, or rather the eccentricity is found to be insensible in consequence of the errors of observation. We shall not underestimate these unknown eccentricities if we assign to them the mean value of the known eccentricities of the satellite orbits (0 0325). Making this maximum assumption we find that the average eccentricity for the solar system—the eight great planets and their twenty-one satellites—cannot surpass 0.0389.

cause the former have been drawn to our system from outer space, while the latter have originated by an anomalous process, and depart so radically from the other bodies of the system that they cannot be considered as a type of planetary evolution, but rather as an abnormal development. It is also to be remarked that the eccentricities of the orbits of the planets and satellites are still involved in some small degree of uncertainty, and moreover they will vary from century to century owing to the cumulative effects of the secular variations and of the long-period inequalities. Notwithstanding these changes it is clear that the values of the eccentricities given above represent the true nature of the solar system

It follows, therefore, that the average eccentricity among the double stars is more than twelve times that found in the planetary system, and this extraordinary result is manifestly the expression of a fundamental law of nature.

The eccentricities of the orbits of the stars discussed in this work are still subject to slight changes, but there is reason to believe that the average value (0482) will never be altered except by a very small quantity. The apparent orbits given in the preceding chapter enable the reader to make a direct inspection of the linear eccentricity, and he may thus judge of the magnitude of this element, as well as of the changes it is likely to undergo. In order to minimize the uncertainty in our final data, we have purposely restricted our researches to the forty orbits which were capable of the most exact determination. Since the orbits of the forty stars will undergo no sensible improvement, at least for a good many years, it seemed of interest to present also figures of the real orbits.

In the accompanying illustrations the orbits are arranged in the order of eccentricity, and the reader is thus enabled to examine the different degrees of elongation. Accordingly, it appears that while the orbits are much more eccentric than those of the planets and satellites, they are yet much less eccentric than those of the long-period comets.

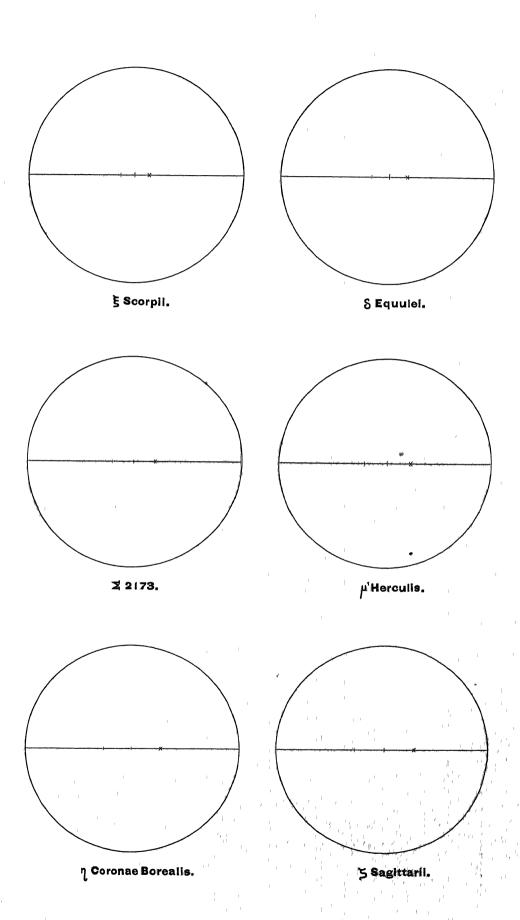

In the preceding diagram we have drawn one broken line to illustrate the

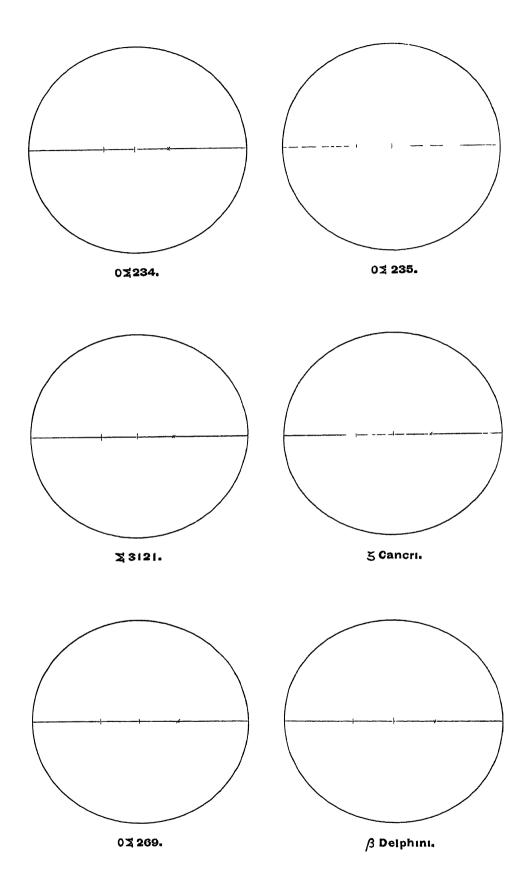

distribution of the orbits of comets, and another for the distribution of the orbits of the planets and satellites The number of cometary orbits is so large that in this case the scale of ordinates had to be very much reduced. spection of these curves shows that the planetary orbits are heaped up about a very small eccentricity, while the cometary orbits cluster around the parabo-This characteristic of the oibits of comets indicates, as lic eccentricity Laplace first pointed out, that these bodies have been drawn to our system from the regions of the fixed stars, and therefore their eccentricities surpass, equal or approximate unity Some of the comets have passed near the larger planets, and thus suffered perturbations which have reduced their eccentricities, and hence the curve slopes down gradually on the side towards the origin The right branch of the curve is but little known, since the great perihelion distance of hyperbolic comets enables them to pass through our system unnoticed, unless they happen to be very bright

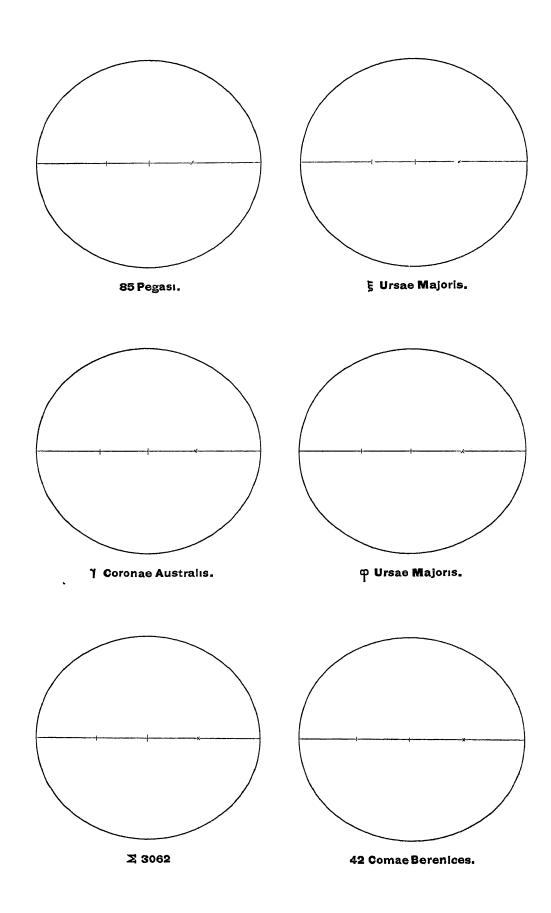

Thus it is evident that the tendency of double-star orbits is to group about a mean eccentricity which is almost equally removed from the two extremes presented in the solar system. Orbits which are so much elongated have no close analogy with those of the planets and satellites, on the other hand their lack of very great eccentricities excludes them from the category of comets, and does not permit us to assign to these systems a fortuitous origin. We shall see hereafter that the orbits were originally nearly circular, in the course of immeasurable ages they have been gradually expanded and elongated by the working of tidal friction in the bodies of the stars. The visible elongation of the orbits thus enables us to trace the changes of the stellar systems through millions of years, and to throw light upon the problems connected with their evolution.

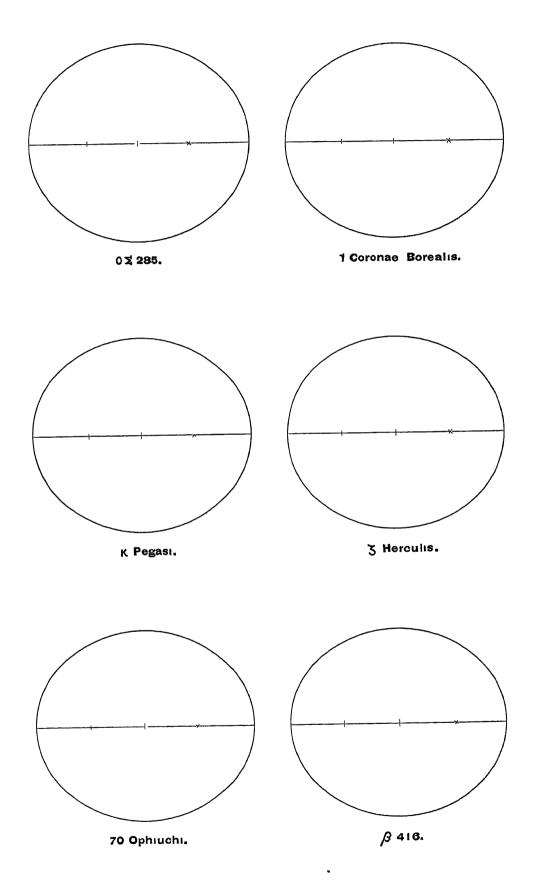

In discussing the motion of  $\gamma Virginis$ , Sir John Herschel long ago remarked that "the eccentricity is, physically speaking, by far the most important of all the elements," and now we see that this element, which depends wholly on micrometrical measures, and is independent of the parallaxes and relative masses of the stars, gives the sole clue to the evolution of the stellar systems, and will some day enable us to lay a secure foundation for scientific Cosmogony

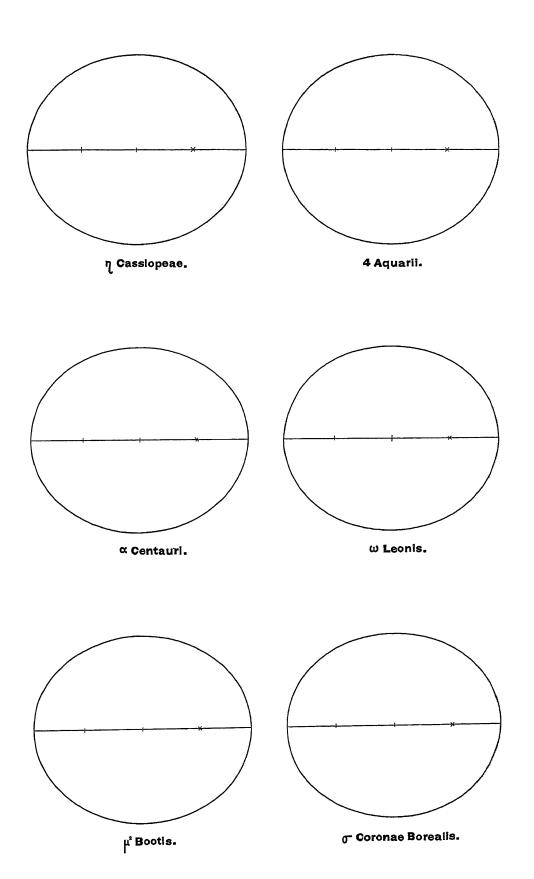

We may observe that besides throwing light upon the past condition of the universe the general law of the eccentricity here established will also be useful to practical astronomers. The eccentricity of any given orbit may depart considerably from the mean here indicated as the most probable value, yet the tendency towards this region will on the whole prove useful to computers

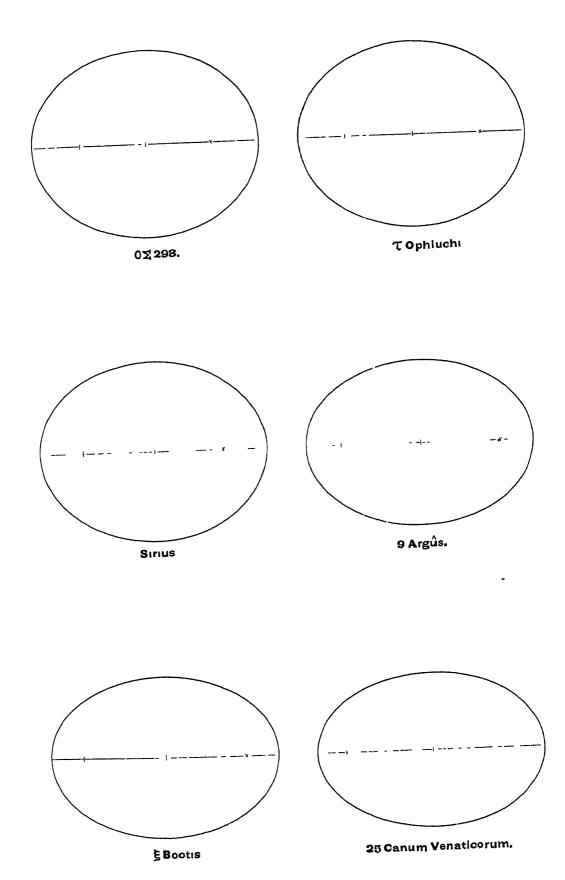

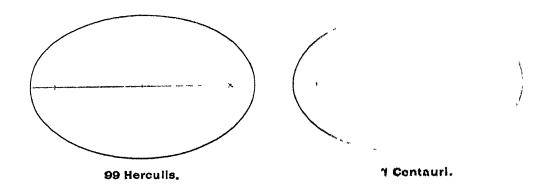

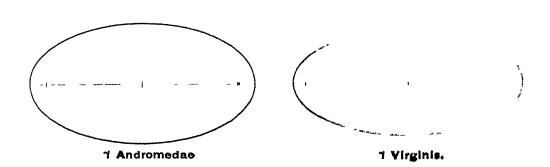

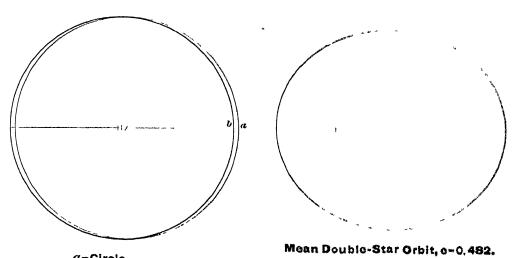

.

a=Circle b=Mean Pianetary Orbit, e=0.0389.

The observer who is aware of the high eccentricities and different inclinations of the orbits will know that in many cases the length of the apparent radius-vector is subject to great variations, and as a shortening of the radius-vector corresponds to accelerated angular motion of the companion, he will never find it safe to assume that the motion is uniform. The forty stars treated in this work present several instances where the angular motion at certain epochs has been extremely rapid, and it is much to be regretted that more observations were not secured at such critical points of the orbits. These general results may prove of value to the observer of the future, and stimulate an increased interest in the systematic measurement of revolving binaries.

### §5 Relative Masses of the Components in Stellar Systems

A problem of fundamental importance in the study of the stars is the determination of the relative masses of the components of a system. Such determinations have been made heretofore in very few cases, and even when undertaken have been seriously embarrassed by the errors of observation. It has been customary to base the investigations upon absolute positions determined with the Meridian Circle. The errors of our absolute positions deduced in this way are so large in comparison with the delicate quantities depending on the irregularity of the proper motions of the individual components of a system whose centre of gravity moves uniformly on the arc of a great circle, that the results obtained are affected by large probable errors

The systems in which such researches have been attempted are

- (1) a Cams Majoris, where  $\Lambda$ UWERS finds the masses to be in the ratio of 1 2 119
- (2) a Centauri, in which Stone found the masses approximately equal, Elkin made them as 1 1124, and Roberts finally concludes from a more elaborate investigation that they are in the ratio of 1 1041.
- (3)  $\eta$  Cassiopeae, investigated in 1881 by Ludwig Struve, who found the masses to be in the ratio of 1 3 731

So far as we are aware these three wide systems are the only ones whose relative masses have been investigated, and we may remark that the condition of each star is favorable to a determination from the circumstance that the pairs are wide and tolerably rapid in their orbital motion, and therefore the

irregularity of the proper motions of the components is conspicuous in comparison with the errors of observation

There are other systems such as 70 Ophiuchi,  $\xi$  Boötis, and  $\gamma$  Virginis, which are favorable for similar investigations, but none have yet been attempted. It would be all the more interesting to investigate the relative masses of 70 Ophiuchi from the circumstance that the system contains a dark body which sensibly perturbs the visible components

In the case of  $\gamma Virginis$  we might infer that the masses are nearly equal, as in the system of a Centauri

But even if the bright and widely-separated pairs were all investigated, it would still be difficult to reach any of the small, close stars whose distances are less than two seconds of arc. The investigation of the relative masses of the components of such systems by means of absolute positions determined with the Meridian Circle seems forever impossible, since the stars under such power would seldom be separated, and when separated the errors of observation would be larger than the quantities involved in the determination of the relative masses. The old method is therefore very limited in its application, and a new method must be invented if we are ever to have precise knowledge of the relative masses of the components of binary systems

We suggest the following method as much more general and also much more exact than the one depending on absolute positions The distance and position-angle of each component with respect to a neighboring star should be determined at different epochs, the measures being taken with the Heliometer if the distance is large, with the Micrometer if the neighboring star is close or A series of such relative positions would disclose the location of the centre of gravity by its uniform motion and the resulting conservation of areas with respect to the neighboring star. And since the measures are differential only, it ought to be possible to attain the desired degree of accuracy; the only difficulty likely to arise in practice would be one depending on the personal equations and the constant errors affecting the work of Experience alone could determine how serious this individual observers difficulty would be, but it seems probable from the results obtained in the measurement of double stars that it would become considerable only in the case of pairs which have no near companion.

Indeed, this method for finding the relative masses of stars is exactly the same as that employed in parallax measurement, except that the observations must extend over the period of a revolution (or a large part of such a period) instead of over the period of one year

The proposed method therefore is as follows. Let the differences in right ascension and declination with respect to either of the components at the epochs t, t't'' be

Let the differences in right ascension and declination of the components of the system in like manner be

$$\Delta \alpha = \rho \sin \theta \sec \delta , \quad \Delta \delta = \rho \cos \theta$$
 $\Delta \alpha' = \rho' \sin \theta' \sec \delta' , \quad \Delta \delta' = \rho' \cos \theta'$ 
 $\Delta \alpha'' = \rho'' \sin \theta'' \sec \delta'' , \quad \Delta \delta'' = \rho'' \cos \theta''$ 

Then the coordinates of the centre of gravity of the system referred to the neighboring star will be given by the expressions,

where the formulæ are arranged for the case of the smaller star, which is generally to be preferred, as the magnitude of the absolute orbital motion about the centre of gravity is in the inverse ratio of the masses of the components

In these expressions the only unknown quantity is the ratio  $\frac{M_1}{M_1+M_2}$  The most natural condition for the determination of this unknown is furnished by the principle of the conservation of the motion of the centre of gravity of a system of bodies. When the arc described by the centre of gravity is small, the motion in right ascension and declination is uniform like that in the arc of a great circle. Thus we have

$$\frac{\varDelta \alpha_0' - \varDelta \alpha_0 + \frac{M_1}{M_1 + M_2} \left(\varDelta \alpha' - \varDelta \alpha\right)}{\varDelta \alpha_0'' - \varDelta \alpha_0 + \frac{M_1}{M_1 + M_2} \left(\varDelta \alpha'' - \varDelta \alpha\right)} = \frac{\varDelta \delta_0' - \varDelta \delta_0 + \frac{M_1}{M_1 + M_2} \left(\varDelta \delta' - \varDelta \delta\right)}{\varDelta \delta_0'' - \varDelta \delta_0 + \frac{M_1}{M_1 + M_2} \left(\varDelta \delta'' - \varDelta \delta\right)} = \frac{t' - t}{t'' - t}$$

When n sets of independent observations have been secured, the number of equations for the determination of the most probable value of the ratio  $\frac{M_1}{M_1+M_2}$  is 2 (n-2)

If the precession is sensible, the observations of  $\theta_o$ ,  $\theta_o'$ ,  $\theta_o''$ , and  $\theta$ ,  $\theta'$ ,  $\theta''$ , etc, must be referred to a common epoch. An independent formula for the determination of the ratio  $\frac{M_1}{M_1+M_2}$  may be deduced from the criterion that the motion of the centre of gravity is confined to the arc of a great circle

While the method may not prove to be entirely general, owing to the occasional absence of suitable comparison stars, there is reason to think that the Heliometer and Micrometer together ought to prove very effective. Such measurements, if extended to groups of perspective involving two or more objects, will furnish the means also of detecting the existence of any possible irregularities in the proper motions of single stars. In the early days of star cataloguing it was difficult to believe that the proper motions were uniform and rectilinear, but as this has been found to be the general rule, it is now difficult for some to credit the existence of irregularities in the proper motions, or the presence of dark bodies perturbing the motions of the stars. The errors of observation are relatively so large that sound method of procedure requires caution in attributing anomalies to foreign causes, lest by undue credulity we be led to introduce all manner of vain fictions; yet it is certainly unphilosophical to doubt the existence of numerous dark companions which disturb the motions of the fixed stars. It will ultimately be a matter of great interest to determine the extent and the character of such perturbations These considerations suggest fields of inquiry of the widest scope, and assure us that while exact Astronomy shall be cultivated, the Heliometer and the Micrometer are not likely to lose their present importance, through the introduction of any sort of mechanical methods

It will be some years before the above method can be applied, and hence it is interesting to reach some general result as to the relative masses of binary stars. The determinations above spoken of, except in the case of Sirius, show that the masses are roughly in proportion to the brightness of the stars. This rule would doubtless lead to erroneous conclusions in a good many individual cases, yet in taking double stars as a class, it will give results which are not far from the truth, and hence the light-ratios of the forty stars given in the Table show that on the average the components of binaries are comparable, and frequently almost equal, in mass. This we may infer to be a general law for all binaries, and the corresponding relative masses accord perfectly with those of the double nebulae drawn by Sir John Herschel, and with the mass-ratios resulting from the rupture of the figures of equilibrium of rotating mass of fluid investigated by Poincaré and Darwin.

### §6 Exceptional Character of the Planetary System

The fundamental result indicated in the foregoing section is in striking contrast with the phenomena presented in the solar system The masses of the planets are very small compared to that of the Sun, and the masses of the satellites are very small compared to those of the planets around which they The mass-ratio in the case of the Earth and Moon amounts to at, and is by far the largest in the solar system. The mass of Jupiter, 1011, 16, is much larger than that of any other planet, and yet such a body is wholly insignificant compared to the Sun If such inconsiderable companions attend the fixed stars, they would neither be visible, nor could they be discovered by any perturbations which they might produce. It is therefore impossible to determine whether the stellar systems include such bodies as the planets, and we are thus unaware of the existence of any other systems like our own the other hand the heavens present to our consideration an indefinite number of double systems, each of which is divided into comparable masses double systems stand in direct contrast to the planetary system, where the central body has 746 times the mass of all the other bodies combined binary stars the mass distribution is evidently double, while in the solar system it is essentially single. By a process extending throughout the universe it seems that the nebulae frequently divide into approximately equal or compaiable masses, and develop into double stars, while in the case of our own nebula substantially all the matter has gone into the Sun

Therefore while observation gives us no ground for denying the existence of other systems like our own, it does not enable us on the other hand to affirm or even to render it probable that such systems do exist. And in this state of insufficient evidence we are confronted by the undoubted existence of a great number of systems of an entirely different type. Whatever theories of Cosmogony are proposed, it is evident that in order to have any claim to acceptance, they must be based upon what is really known, not upon what may or may not exist. Those who have proceeded to deduce Cosmogonic processes from our own isolated and abnormal system, have therefore pursued an illogical course, and it is not remarkable that they have failed to throw much light upon the laws of Cosmogony.

The solar system is rendered abnormal by the great number and small masses of its attendant bodies and by the circularity of their orbits about the large central bodies which govern their motion. The system is throughout so

regular, and adjusted to such admirable conditions of stability, that among known systems it stands absolutely unique. Whether observation will ever disclose any other system of such complexity, regularity and harmony, is an interesting question for the future of Astronomy. It is certain that the number of double stars will be augmented in proportion to the diligence of observers and the improvement of our telescopes, and we may reasonably expect a sensible increase in the number of triple and quadruple stars and of stars attended by dark bodies.

Such systems as Sirius, Procyon,  $\zeta$  Cancri and 70 Ophiuchi are not likely to be isolated cases; but caution is required where the observations are not decisive, lest the number be unduly increased by imaginary bodies resulting from errors of observation. It seems probable that a number of double stars are likely to disclose perturbations which can be investigated, and we have already some indications that the motions of  $\zeta$  Herculis,  $\xi$  Ursae Majoris,  $\mu^1$  Herculis and  $\eta$  Coronae Borealis are not perfectly regular. But in the present state of the measures it seemed best to attribute the apparent irregularities to errors of observation.  $\zeta$  Herculis especially merits the most careful attention of observers; after its periastron passage a refined investigation will show whether the motion is really perturbed.

The question naturally arises whether the stars of these double systems are attended by small dark bodies of a planetary character. We have seen that most of the binaries have highly eccentric orbits, and hence if planetary bodies revolved around either component, they would experience great perturbations, besides the most violent changes of light and heat. It seems probable that planets could not be formed without developing very eccentric orbits, and if once in existence, it is questionable whether such bodies could endure under the violent perturbations to which they would be subjected at periastron Even if a planet were very close to its central star, its motion would be affected by an inequality of enormous magnitude analogous to the annual equation in the moon's motion; and if not destroyed by collision with one of the stars or by disintegration under the tidal forces within Roche's limit, in all probability it would sooner or later be driven from the system on a curve analogous to a parabola or an hyperbola. Thus, while the motion of a planet around one of the components could hardly be so stable as the corresponding phenomena of the solar system, it might yet continue for long ages if the orbit of the binary be not too eccentric; the final state of the system would depend upon the densities, relative masses and distances of the components, the mutual inclinations, and above all, the eccentricities, of their orbits
